The Clinical Significance of So-Called Chronic Appendicitis*†

By JULIUS FRIDENWALD, M.D., F.A.C.P., and THEODORE H. MORRISON, M.D., F.A.C.P., Baltimore, Maryland

ANY conflicting views concerning the significance of chronic appendicitis have been held during the past 10 to 15 years. While some clinicians have attributed many disturbances occurring in the abdomen to this cause, others have held that it in itself has but slight clinical significance. According to the latter conception, so-called chronic appendicitis is not a disease in which the symptoms are due entirely to the appendix alone, but one in which many other abdominal as well as other factors play an important rôle.

It is a well recognized fact, that since the advent of roentgenology numerous variations in the size, shape and position of the appendix have been observed, which have been recorded as chronic changes in this organ. In a considerable number of these reports, great significance has been attached to these findings as a probable cause of many digestive symptoms. Operation has been frequently undertaken upon the basis of

*From the Gastro-Enterological Clinic of the Department of Medicine, University of Maryland.
†Delivered at the Baltimore Meeting of the American College of Physicians, March 23, 1931.

If the embryology of the appendix is carefully studied, the cause of many errors in diagnosis becomes apparent. This organ is derived from the cecum as a pouch about the seventh or eighth week of fetal life. The cecum occupies a high position under the liver during early development but descends lower later and drags the appendix down with it. The appendix finally assumes its position in the right iliac fossa, but the attachment to the cecum may vary markedly. In 90 per cent of instances, according to Treves, it occupies a mediodorsal position. The direction of the appendix is determined by the position of the attachment as well as the length of the mesoappendix. It may be directed posterior or lateral to the cecum and colon or into the pelvis beneath the terminal ileum or upward in the direction of the gall bladder. The meso-

appendix may vary in shape and position and may determine certain peculiarities in the clinical manifestations of the diseased appendix. It is evident, that many of the variations in shape, size and position of the appendix may be due entirely to embryological conditions, presenting in no manner evidence of inflammatory processes, and are entirely compatible with normal health. Furthermore, when chronic disease of the appendix actually does occur, it is a well recognized fact, that this often represents but a part of the disease of the entire digestive tract. Gastro-intestinal infections rarely occur as single lesions, but are usually multiple and such affections as chronic appendicitis, chronic cholecystitis and peptic ulcer are not uncommonly associated. Heyd, Killian, and MacNeal,¹ and, more recently, Deaver,² attribute the primary inflammation in most instances to the appendix from which extension takes place into the liver and finally into the gall bladder. The formation of peptic ulcer may also represent a stage in this process. Inasmuch, therefore, as chronic gastro-intestinal infections extend gradually throughout the entire digestive tract the symptoms must vary according to the sites most markedly involved in the infection as well as with their anatomical and physiological characteristics. It is evident that an organ with a small outlet like the appendix or a small duct like the gall bladder might produce more severe manifestations as a result of infection than a large organ such as the liver. A knowledge that these infections often involve numerous areas of the digestive tract simultaneously will not

infrequently explain the development of new symptoms or the persistence of old ones.

Inasmuch as the appendix is constituted with a small lumen, when undergoing chronic inflammatory changes it will necessarily have its function interfered with. The contents of the cecum will enter the appendix under these conditions and decomposition take place with damage to the muscular wall. This will finally lead to disturbances of the functions of the cecum and ileum with extension into the colon, frequently increased by the deforming complications due to adhesions.

In this connection the work of Rohdenberg³ is of interest. In a pathological study of a large number of chronic appendices, he noted that the first changes occur in the tip, consisting of round cell infiltration about the Meissner ganglia, which increases until the ganglia are completely buried in round cells. Fibrosis now takes place until the ganglia are enveloped in dense fibrous tissue. From these observations he concludes that so called chronic appendicitis is a productive inflammation originating as a lesion of the sympathetic nervous system, which is not restricted to the appendix alone but involves the splanchnic sympathetic nervous system in general. According to Rohdenberg, the nerve lesions would explain reflex gastric symptoms such as attacks of spasm in the gastro-intestinal tract and pain, as well as the frequent absence of relief following appendectomy.

In order to establish the presence of chronic appendicitis, advantage is usually taken of a roentgen ray study

This method of investigation is, however, so extremely delicate that many unsuspected findings, such as slight delay in emptying, varying shapes and obliteration of the lumen are frequently noted, which in themselves have but slight significance. The most constant x-ray findings of chronic appendicitis are tenderness over the region of the appendix, frequent changes in shape abnormal and fixed position. The tenderness which is produced over the visualized appendix when moved under the palpating hand is of considerable value, being far more important than the tenderness ordinarily noted over McBurney's point when palpating the abdomen. This sign is often present during the recurrent attacks but usually disappears in the interval. Changes in shape of the appendix due to kinking and fixation from adhesions which are usually classified as important roentgenological findings may, however, be of but slight clinical significance. Other remaining signs are of even less importance. Of these, attention must be directed to abnormal filling. There is as yet so marked a disagreement as to the significance of filling or nonfilling of the appendix, that this sign must be at present entirely disregarded.

Brown and Gaither¹ call attention in the visualization of the appendix to its changes in shape as well as to the pain produced on palpation under fluoroscopic investigation as important evidences of chronic appendicitis. They consider these findings, when taken into consideration with the clinical history, as well as subjective and objective findings of the greatest value in diagnosis.

Of indirect signs, disturbances of the ileum and cecum must be considered. Ileal and cecal stasis may be caused by adhesions arising from the appendix, but according to White,² are not always due to this condition and may occur also as the result of atony and ptosis of the bowel. Pyloric spasm is frequently noted, but is of slight diagnostic importance. The roentgen ray records, therefore, many changes which are in themselves of slight clinical significance. These signs can therefore be utilized only as confirmatory evidence of chronic appendicitis and must be considered of value only when taken into consideration with the clinical manifestations of the disease. However, the x-ray may be of considerable aid in diagnosis in eliminating the presence of other affections.

Further confusion has arisen in diagnosis due to pathological studies of the appendix itself. No less an observer than Aschoff has directed attention to the occurrence of chronic inflammatory changes in the appendix in three-quarters to four-fifths of all individuals in the sixth and seventh decades of life. On the other hand, these findings, valuable as they may be, are in themselves, not of sufficient evidence to indicate that all such lesions are necessarily associated with symptoms. As a matter of fact, an individual may continue on throughout life with changes of this type without manifesting any evidence of the slightest discomfort. Aschoff, as well as many others, maintains that all cases of chronic appendicitis occur as the result of former acute attacks, though it is difficult to obtain a history of this

condition in many instances. A patient may have forgotten a previous attack, for many of these occur during childhood, and are overlooked or may have been of so mild a type as to escape detection. On the other hand, Deaver is firmly convinced, that not all chronic appendices are the result of previous acute disease, but may be due to a low-grade intestinal infection. According to our experience, one should hesitate in arriving at the diagnosis of this affection without a previous history of an acute or of recurrent attacks.

The clinical signs of chronic appendicitis are rarely distinctive. The pain and tenderness in the right lower quadrant may be due to other causes and in most instances localizing symptoms are absent. The gastric symptoms noted so frequently, such as loss of appetite, fullness, acidity, regurgitation, nausea and vomiting are due to pylorospasm and are not infrequently observed in other affections, as for instance, in gall bladder disease, and are by no means characteristic of chronic appendiceal disease. On the other hand symptoms apparently caused by chronic changes in the appendix are in many instances not produced by this condition itself, but are often the result of a general constitutional asthenia not uncommonly associated with visceroposis, a mobile right colon, movable cecum, mucous colitis, or ileal stasis. At times they may even be due to peptic ulcer or gall bladder disease. Case⁶ has shown from a study of his patients, who continued to complain of right lower quadrant pain following appendectomy, that in a large number of these cases, the etiology was found to be in the pelvic colon and rectum.

Pelvic tumors, carcinoma, diverticulitis, hemorrhoids and enterospasm constituted the most common causes in his cases.

Carnett,⁷ has more recently demonstrated that patients affected with so-called chronic appendicitis are usually not the subjects of this condition, but of more or less generalized disturbances involving the digestive tract, as well as the abdominal wall. According to him, this affection is most commonly observed in constitutionally predisposed individuals and occurs most frequently in the asthenic or visceroprotic neurotic type. It is on this account, that removal of the so-called chronic appendix is often ineffective in affording relief from the symptoms.

According to Carnett, the most frequent cause of pain and tenderness in the right lower quadrant of the abdomen is not to be found in the abdomen itself, but in the abdominal wall. It is due most frequently according to him, to neuralgia and less often to chronic strain of the lumbar spine and sacro-iliac joints. The method suggested by Carnett of differentiating between intra-abdominal and parietal tenderness is based on palpation of the abdominal wall following alternate relaxation and contraction. "Tenderness which is elicited over relaxed muscles may be either parietal or intra-abdominal in origin. Tenderness present with relaxed muscles and absent with tensed muscles is due to a subparietal lesion, and its cause should be sought inside the abdomen. Tenderness which is found both when the muscles are relaxed and when they are voluntarily tensed is due to an anterior

parietal lesion and its cause should be sought outside the abdominal cavity”

Carnett demonstrates the parietal location of the pain by determining tenderness “(1) by pinching abdominal skin and fat, (2) on finger-end poking of the abdominal wall, while the patient holds his abdominal muscles tense either by forcible contraction of the diaphragm or by raising and holding his heels above the bed with knees extended, (3) on making pressure over intercostal nerve trunks, and (4) on pinching or exciting finger-end pressure over Poupait’s ligament and over the upper posterior buttock region on the right side” In order to obtain the best results, Carnett advises that these tests be carried out with considerable force. Since we have been utilizing the method of examination as advised by Carnett, it is surprising to note, how many suspected cases of so-called chronic appendicitis are found actually to be due to extra-visceral disease. In his studies Carnett rejects completely the theory of Head, Mackenzie and others of the visceroparietal reflex which, according to him, has resulted in numerous errors in diagnosis and ineffective operations.

It is evident, that the diagnosis of so-called chronic appendicitis is fraught with considerable difficulty and should be arrived at only following a careful intensive study. It is also doubtful whether this condition can actually occur except when preceded by an acute attack.

Inasmuch as the only definite direct evidence of chronic appendicitis from a clinical standpoint is in the complete relief afforded following the therapeutic test—appendectomy, it becomes a

matter of extreme difficulty to estimate the actual incidence of this affection. According to our observations, which are largely in accord with those of Bettman,⁸ this must be far less than has ordinarily been held.

On the other hand, however, Deaver² maintains that chronic appendicitis is just as much a distinct clinical entity as chronic peptic ulcer or chronic cholecystitis. Inasmuch as it occurs associated with practically all forms of abdominal lesions, as for instance, chronic cholecystitis and chronic peptic ulcer, it must be regarded, according to him, as a factor of importance in the etiology of these affections. It is possible, that it is the original focus from which the infection extends. The fact that all patients who are operated on for chronic appendicitis are not relieved of all of their symptoms, by no means proves, according to Deaver, that no such entity exists. He is so strongly impressed with the necessity of removing every chronically diseased appendix or even a suspected one, that he considers it a grave error to expose the patient to the unjustifiable risk of not operating. For, according to him, even though the symptoms of which the patient complains are not overcome by this procedure, he is assured against future attacks as well as of complications.

In summing up the results of these observations, it is quite evident that conflicting views are still held regarding the clinical significance of so-called chronic appendicitis. While on the one hand, some maintain that this condition cannot be regarded as a definite clinical entity, others hold quite as firmly the contrary view. When one contem-

The Clinical Significance of So-Called Chronic Appendicitis*†

By JULIUS FRIDINWALD, M D, F A C P, and THEODORE H. MORRISON,
M D, F A C P, *Baltimore, Maryland*

MANY conflicting views concerning the significance of chronic appendicitis have been held during the past 10 to 15 years. While some clinicians have attributed many disturbances occurring in the abdomen to this cause, others have held that it in itself has but slight clinical significance. According to the latter conception, so-called chronic appendicitis is not a disease in which the symptoms are due entirely to the appendix alone, but one in which many other abdominal as well as other factors play an important rôle.

It is a well recognized fact, that since the advent of roentgenology numerous variations in the size, shape and position of the appendix have been observed, which have been recorded as chronic changes in this organ. In a considerable number of these reports, great significance has been attached to these findings as a probable cause of many digestive symptoms. Operation has been frequently undertaken upon the basis of

this observation alone. As the result of this procedure, namely, appendectomy, unfavorable outcomes have been recorded in many instances. These failures have led to a further study of this subject. As a result the McBurney incision has now ordinarily been discarded, and other abdominal disturbances have often been observed as the cause of the symptoms.

If the embryology of the appendix is carefully studied, the cause of many errors in diagnosis becomes apparent. This organ is derived from the cecum as a pouch about the seventh or eighth week of fetal life. The cecum occupies a high position under the liver during early development but descends lower later and drags the appendix down with it. The appendix finally assumes its position in the right iliac fossa, but the attachment to the cecum may vary markedly. In 90 per cent of instances, according to Tieves, it occupies a medioposterior position. The direction of the appendix is determined by the position of the attachment as well as the length of the mesoappendix. It may be directed posterior or lateral to the cecum and colon or into the pelvis beneath the terminal ileum or upward in the direction of the gall bladder. The meso-

plates the many instances in which so-called chronic appendices have been removed without affording even the slightest relief on the one hand, and many others in which symptoms have occurred for years followed by almost immediate as well as permanent relief by this procedure on the other, the cause of the conflicting views concerning the significance of this condition becomes apparent. It is quite evident, therefore, that it is impossible to draw general conclusions, but that each case must be considered individually and only following prolonged and most careful study can final conclusions be arrived at leading to the proper method of procedure to be undertaken.

Finally, it must be held in mind that distress in the right lower quadrant alone is in itself by no means sufficient evidence as an indication for operation, and that unless there is a direct history of preceding acute attacks, doubt as to diagnosis must be maintained unless the other factors present point overwhelmingly in favor of this procedure. In a study of 100 cases in which appendectomies had been performed for so-called chronic appendicitis with unsuccessful results, the following diagnoses were finally established:

	No. of Cases
Peptic Ulcer	24
Cholecystitis and Cholelithiasis	21
Renal and Ureteral Disease	4
Pelvic Disease	2
Colitis	11
Neuralgia of the Abdominal Wall	14
Carcinoma of the Cecum	2
Tuberculosis of the Cecum	1
Abdominal Adhesions	19
Hernia	2
	—
Total	100

The following brief case reports may be of interest as indicating mistaken diagnosis as to so-called chronic appendicitis.

Case 1 Male, aged 27, digestive disturbance for years with abdominal colic, right lower quadrant discomfort and tenderness, diagnosis of chronic appendicitis, appendectomy performed, no relief, finally, complete recovery after treatment for mucous colitis, which evidently had been present for years.

Case 2 Female, aged 39, attacks of right-sided abdominal discomfort for years, beginning after birth of first child and occurring at irregular intervals, no discomfort or indigestion during intervals, tenderness in lower right abdomen, diagnosis of chronic appendicitis, McBurney incision, Chronic appendix removed, return of discomfort, three months' pain, gradually more violent, extending into upper right quadrant, diagnosis cholelithiasis, second operation, gall bladder removed filled with stones, complete recovery.

Case 3 Male, aged 25 years, indigestion for years, discomfort several hours after meals, usually relieved by food and alkalis, acid eructations, lower right discomfort and tenderness, diagnosis of chronic appendicitis with reflex stomach disturbance. Operation appendectomy, relief for one year, return of symptoms, more intense, gastric hemorrhage, tarry stools, x-ray confirmed diagnosis of pyloric ulcer, medical treatment, complete recovery.

Case 4 Male, aged 56, frequent attacks of lower right-sided pains for years, always some discomfort in this region, tenderness in the lower right quadrant, slight urinary discomfort, urine found normal, operation, chronic appendix removed, no relief, severe attacks of pain in six months, bloody urine, cystoscopic examination revealed ureteral stone near bladder, removed intravesically, complete recovery.

Case 5 Male, aged 44, right-sided pain for years with tenderness in that region, flatulency, eructations, fullness and pain following meals, relief in the recumbent posture, diagnosis, chronic appendicitis, appen-

dectomy, no relief, small epigastric herma discovered after years second operation, repair of herma, complete relief

On the other hand the following cases illustrate the great value of appendectomy in certain instances of chronic appendicitis

Case 1 Male, aged 10, discomfort in lower right quadrant of a mild type for years, indigestion with pressure, fullness following meals, eructations, flatulency, occasional nausea, loss of flesh, loss of appetite weak, nervous, unable to work, tenderness constantly in right lower quadrant, no definite history of former acute attacks, appendectomy, entire relief of symptoms, gradual recovery from weakness; gain of 20 pounds after three months, complete and lasting recovery

Case 2 Female aged 31, lower right quadrant pain for years with tenderness in this area, movable right kidney, pain more intense at menstrual periods, occasionally pain violent, requiring morphia for relief, various diagnoses made, ovarian disease, ureteral stricture, renal colic, many ureteral dilatations without relief, finally appendectomy performed, a chronic appendix removed, complete restoration of health

Case 3 Male, aged 51, affected with lower right-sided pain for years, never free from discomfort, no history of acute or recurrent attacks, tenderness over McBurney's point, appendectomy advised, unwilling to submit to procedure, sudden violent fulminating attack after 5 years, immediate operation, appendix removed revealing evidence of chronic inflammatory changes and gangrenous tip, many adhesions, stormy recovery, complete relief

Case 4 Female, aged 26, indigestion for years, pain in stomach occurring two hours following meals, relieved by food and alkalis, acid eructations, slight tender epigastric area occasional discomfort and tenderness in the lower right quadrant, test meal revealed hyperchlorhydria, x-ray showed small defect at pylorus and lower right quadrant adhesions, thorough ulcer treatment instituted, no relief, discomfort

in lower right abdomen more intense, tenderness in this region, appendectomy performed, curled up appendix removed contained concretions, complete recovery both from local and dyspeptic symptoms

Case 5 Female, aged 41, discomfort in right side for many years, occasionally colicky in type, tenderness in this region, never fever, considerable mucus discharged in stools in the form of shreds and bands, severe constipation, diagnosis mucous colitis, various treatment instituted, irrigations of many varieties, temporary relief only, tenderness in right side more intense, appendectomy advised, a chronic appendix with many adhesions removed complete recovery from discomfort, no further evidence of mucous colitis

CONCLUSIONS

From a careful review of the literature as well as from our observations extending over a large series of cases the following conclusions seem justified

1 Chronic appendicitis when considered purely from a clinical standpoint is not as is usually held. That it does, however, occur is evidenced by the complete and permanent relief at times afforded by means of appendectomy

2 The symptoms produced by so-called chronic appendicitis usually occur as (1) the result of either widespread disturbance involving other abdominal organs not limited to the appendix itself or as (2) forms of neuralgia occurring in the abdominal wall. The method of examination as advised by Carnett should always be followed in differentiating these conditions

3 The roentgen ray signs are usually misleading and difficult of interpretation, and can therefore be regarded as of minor significance only

4 Individualization is of paramount importance. The diagnosis should

never be made except following prolonged intensive study of the patient and should always be regarded with

suspicion unless a history of preceding acute or recurring attacks can be elicited

Early Diagnosis of Neoplasms of the Digestive Tract*

By THOMAS R. BROWN, M.D., F.A.C.P., *Baltimore, Maryland*

I THINK we will all agree that the final aim of Medicine is the prevention or cure of disease—that our studies in gross and microscopic pathology, in bacteriology and in the ever-widening fields of biochemistry and biophysics have this as their ultimate goal. The age of therapeutic nihilism is past, we are no longer satisfied with etiology, pathology and diagnosis, therapy, be it psychical or physical, dietetic, pharmaceutical or surgical, is at last the *ultima thule* for which we are striving.

Perhaps there is no group of diseases in which therapy has been so bitterly disappointing as the malignant new growths of the digestive tract—for in this field relatively early diagnosis is essential if there is to be any chance of success of surgical removal—our *only* effective means of treatment at the present writing and it was but a few years ago that one of the masters in gastro-enterology, Boas, said, "No one can make an early diagnosis of digestive cancer—one must be satisfied with a correct *late* diagnosis."

In a sense this is true for there must be a period of latency, symptom-free, in the evolution of every neoplasm

when diagnosis is impossible except by the veriest accident. On the other hand the more we have studied these cases—and they have been the cause of our intensive study ever since the founding of our Clinic eighteen years ago—the more we are convinced that a relatively early diagnosis is possible in many cases, antedating by months, and sometimes by a year or more, the time when the diagnosis had been finally made, and that in many cases it was this fatal delay that spelled the difference between hopelessness and potential success.

Cancer is met with more frequently in the digestive tract than anywhere else in the body, it is definitely on the increase, an increase not to be explained by better methods of diagnosis or by the steady increase of the average age of man, but a true increase apparently due in some way to the accidents and incidents peculiar to an increasingly complex civilization. Is it due to new forms of trauma? Is it in any way due to increasing mental and nervous strain? Does our modern diet play a rôle? No one can prove that it does and yet Hoffman has found marked infrequency of digestive cancer among the primitive tribes of South America, McGarrison meets with practically no cases in the 400 to 500

*Delivered at the Baltimore Meeting of the American College of Physicians, March 23, 1931.

abdominal operations that he has performed yearly on the natives of the hills of Northern India, and Lane is firmly convinced that excessive consumption of meat, especially pork, and lessening intake of raw and rough foods with its inevitable lessening of motor activity of the large intestine, play a major rôle in the etiology of neoplasms of the digestive tract

But to the vast majority of students in this field, no satisfactory explanation has been found for its cause or its increase. Why is it so much more prevalent in some countries than in others? Is it contagious? May there be a hereditary factor? The work of Wells and Slye on white mice suggests this possibility and recent statistical studies, notably those of Wassinck from Norway, are hard to interpret otherwise

Again, there is considerable evidence that in other parts of the body trauma plays a causative rôle, as, for example, the neoplasm of cotton-spinners and chimney sweeps, of workers in certain aniline dyes and tar, those due to parasites such as *Bilharzia*, *Schistosoma* and the *Spiroptera neoplastica*, and the skin cancers after exposure to the x-rays. There is, however, no evidence that metabolic disturbances or lack of vitamins play any part in its etiology

But none of these facts or factors are of any help to us in diagnosing digestive carcinomata and we must depend on other means of attack. We do not know its cause and therefore we have no means of preventing its development, and so our hope lies in a relatively early diagnosis and early and bold surgery

Cancer of the *oesophagus* should be ideal for surgical treatment were it not for the great technical difficulties involved. Diagnosis is made early. Progressive difficulty of swallowing in the middle aged or old should always make us suspicious, while oesophagoscopy and x-ray studies will usually confirm the diagnosis. It must not be forgotten, however, that intermittent dysphagia such as is usually met with in oesophagospasm occasionally occurs in new growths as well and must be ruled out by similar methods and by other means, notably the much less degree of oesophageal dilatation in the case of cancer

These cases give early symptoms, they develop slowly and metastasize late, they are simply waiting for a technique for successful removal. Robert Miller has performed successful oesophagectomies on dogs, but in the cases in which he and others have operated on human beings, all have succumbed to mediastinal infection. And yet, I know the time of their successful removal lies in the very near future. One has but to remember the almost insuperable technical difficulties that have been so brilliantly overcome in brain and thoracic surgery, fields that seemed equally hopeless but a short time ago, to feel that it is but a question of time before the skill and persistence of our surgical brethren will conquer this field as well. Until then, palliative treatment is all that we can employ, for radium and x-ray therapy and treatment with colloid metals have all proven woefully disappointing

In the case of new growths of the *stomach* the problem is essentially different, removal, successful complete

removal is possible, but to make this possibility a reality, early diagnosis is essential. In making this early or if you will, relatively early diagnosis—for the life span of gastric cancer is possibly *not* the usually accepted one-half to one and a half years but from one to three or four years and what we regard as the first act is in reality the second or third—the history of the case is of more importance than any or all other factors, for after all, unless we suspect, we will not thoroughly investigate.

In an analysis of all our cases of gastric carcinoma for a period of fifteen years less than 5 per cent gave a previous history suggesting ulcer, about 10 per cent had had previous vague gastric symptoms, 85 per cent had had absolutely *no* previous digestive symptoms and it must be this fact—this development *de novo* of digestive symptoms, usually but not always in persons of middle or later life, coming on with no obvious cause and not yielding to symptomatic treatment—that at the present writing at least is our one most valuable means of suspecting or diagnosing gastric cancer and in making us pursue those intensive studies—gastric contents for dropping acid or achlorhydria with special studies as to the soluble protein contents, stool for occult blood, radiography and, especially, repeated and careful fluoroscopy—which in most cases should give us our diagnosis and tell us whether we are dealing with cancer or with one of those conditions with which it is most likely to be confused, chronic biliary tract disease, gastric lues atypical ulcer or pernicious anemia. The tragedy of gastric can-

cer is that its seat of election is not pylorus or cardia, but in the vast majority of cases the lesser curvature, the silent area, where it may grow for a surprising length of time and reach a very considerable size before producing symptoms sufficient to make the patient consult his physician. These symptoms are in no wise characteristic or even suggestive in themselves—usually a slight loss of appetite, some discomfort or fulness, sometimes pain, occasionally slight nausea, in other words those of an ordinary banal dyspepsia—but, and this is the crux of the matter, appearing without cause and *not* disappearing under appropriate symptomatic treatment.

In that very small group of ulcers developing into cancer, 5 per cent in our series, only 11 per cent and 34 per cent in the last two large German series, a *lessening* of appetite, a dropping of acid, persistence of occult blood in the stool, should arouse our suspicion.

It is quite impossible to tell from the size of the growth or the length of the history whether it is operable. Some metastasize early and these are obviously hopeless, a few grow to a considerable size and still remain a local problem only, but obviously in all cases the chance of success depends upon the earliness of diagnosis. I am more and more convinced that it is wiser to operate on a well-grounded suspicion than to wait for a diagnosis beyond criticism. At present we have had more than 50 cases in which surgery seemed justifiable and in about one-half of these the results were promising, one case living fifteen years, several more than ten years and the

rest from two to five years after the operation. We have had no success with any other form of therapy, radium, x-ray, colloid lead, colloid selenium. Incidentally, none of our cases, however extensive the gastric resection, has developed a blood picture suggesting that of pernicious anemia, these results agreeing with those of Henschel of Basle in 77 cases of subtotal gastrectomy.

In new growths of the *small intestine* it is practically impossible to make an early diagnosis, for with the liquid contents and its rapid passage, signs of obstruction must come late, and even then are difficult to recognize—pain, gaseous distention, delay of the barium column, distension of the gut with gas above a definite point as seen in the fluoroscope.

Fortunately the condition is extremely rare—Rankin and Mayo had only 31 cases from 1919 to 1929 at the Mayo Clinic, while in this same ten year period, there were 2,775 cases of cancer of the large bowel and 2,646 of the stomach. The relative lateness of the diagnosis was shown by the fact that whatever the operation, no patient lived more than three years and the average duration of life after the operation was less than one year.

On the other hand, in the case of cancer of the *large bowel*, we have our best opportunity of combining early diagnosis and potential surgical cure, for here we have semi-solid intestinal contents, a much slower passage, a short well defined tube and obviously much earlier and more easily localized obstructive or ulcerative phenomena, while our means of confirming the diagnosis are much more exact.

And yet, a few years ago, I had 9 consecutive cases incorrectly diagnosed, cases with symptoms lasting from six to eighteen months and wrongly diagnosed as mucous colitis, intestinal neurosis, chronic constipation or gastric dyspepsia, for, just as in rare cases of gastric cancer, the symptoms may be entirely intestinal, so in a few cases of intestinal neoplasm, the predominant symptoms are gastric. But, in every one of these cases, malignancy should have been suspected almost from the very first for in every case the symptoms represented various manifestations of large intestinal obstruction, progressive or intermittent, and in every case the symptoms came out of a clear sky with *no* previous intestinal symptoms, in every case the diagnosis could have been anticipated by many months if, and this is essential, the possible cause had been suspected and simple confirmatory methods used—careful abdominal palpation, in a hot bath if the wall is rigid, study of the stool for occult blood and pus, digital rectal and sigmoidoscopic and proctoscopic examinations and very careful X-ray studies, especially fluoroscopy with the barium enema and ruling out by the proper methods tuberculosis, lues, ulcerative colitis, polyp and post-operative adhesions. A persistent filling defect, persistent occult blood in the stool, although obviously it is better, although not often possible, to make the diagnosis before ulceration is present, sometimes a palpable tumor, these with the local and general symptoms, must and usually can give us our correct diagnosis.

From our intensive clinical studies in this field for nearly twenty years, we are convinced

First that there is no test, no laboratory technical method, that is as valuable in diagnosing gastro-intestinal neoplasms as a careful analysis of the history of the case—discarding no symptom because it may seem insignificant. It is upon the art, not the science of medicine, that we must lean, that nice balancing of the facts, that keen judgment in their interpretation, that careful weighing of cause and effect, in other words those highly developed qualities that spell the real clinician. With this as our foundation, we can make a surprising number of relatively early diagnosis if we utilize in addition all the other means at our command, especially careful palpation, the study of gastric contents and stool, the use of instruments for direct study and the x-ray, especially fluoroscopy.

Second, at the present writing surgery, radical surgery, offers our *only* hope of cure, but to make this possible or probable early diagnosis is essential. It is far wiser to explore on a well grounded suspicion than to wait for an absolute diagnosis when all too often metastasis and extension of the growth makes complete surgical removal impossible.

But after all, it is not upon the shoulders of the consultant, the specialist or the surgeon that the responsibility for making the early diagnosis of digestive neoplasms lies, but upon those of that great body of internists and general practitioners to whom the patients come first with their symptoms—symptoms rarely characteristic, often very mild, usually simulating simple functional disturbances in their early phases—but in the majority of cases having one quality in common, one motif that runs through this dance of death, that there had been no history of previous digestive disturbances, that they appeared without apparent cause, that they did not yield quickly to symptomatic treatment. It is this development *de novo*, this progression irrespective of treatment that should arouse our suspicion as to possible malignancy and that should make us utilize every scientific method at our command to confirm or refute this possibility. This, and this only, seems to me at the present writing to be our only possibility of making an early diagnosis, and with this early diagnosis or probability, of materially diminishing the appalling mortality and of appreciably increasing our percentage of permanent cures by the only successful mode of treatment—early, bold, radical surgery.

Studies on the Mechanism of the Pain of Peptic Ulcer*†

By FRED M. SMITH, M.D., F.A.C.P., and W. D. PAUL, M.D., *Iowa City, Iowa*

VARIOUS explanations have been given for the pain of peptic ulcer. In general, however, there are two prevailing conceptions. One is primarily concerned with the irritating action of the hydrochloric acid of the gastric juice on the exposed nerve endings in the ulcer. The other places the emphasis on the altered motor function as represented by spasm, particularly of the pylorus or pyloric sphincter, hyperperistalsis or a combination of these factors producing increased gastric tension.

Talma¹ was one of the first to study the mechanism of gastric pain by the introduction of acid into the stomach. Bonninger,² Heinecke and von Selms³ reported the reproduction of the pain of gastric ulcer by the administration of varying strengths of hydrochloric acid, whereas, in normal individuals, the results were negative. Sippy,⁴ later championed the acid theory of the production of the pain in peptic ulcer. He furthermore believed that the corrosive action of the acid interfered with the healing of the ulcer which

was the basis for the alkali therapy in his well known treatment.

Palmer⁵ has more recently investigated the influence of acid on the pain of peptic ulcer. He administered through a Rehfuess tube, 200 cc of a 0.5 per cent hydrochloric acid. If the pain was not reproduced within thirty minutes, another 200 cc was added. The same amount was occasionally administered the third time. The results are tabulated in three groups. The first is concerned with normal individuals in whom the results were uniformly negative. The second pertains to the study of twenty-five patients with ulcer in whom the typical distress was not induced. Only four of these were said to be in a "distress period." He defines a "distress free period" as one in which spontaneous pain was not experienced during the twenty-four hours preceding the test. The last group deals with eighty-four cases in which the pain was induced by the administration of the acid. In this series the distress was reproduced in 324 of the 404 attempts. Seventy of the eighty failures occurred during the distress free period. It is evident, from the above results, that unless the pain is occurring at frequent intervals, it is not possible to induce it by the

*From the Department of Internal Medicine, State University of Iowa.

†Delivered at the Baltimore Meeting of The American College of Physicians, March 23, 1931.

repeated administration of 200 cc of 0.5 per cent hydrochloric acid

The roentgenological examination in peptic ulcer directed attention to the possibility of spasm and hyperperistalsis contributing to the production of the pain. Hurst⁶ was one of the first to emphasize the importance of increased gastric tension in the production of the distress. He concluded, from an experimental and clinical study that the mucous membrane of the stomach is insensitive to stimulation from dilute hydrochloric acid and dilute organic acids. He, furthermore, stated that the surface of a gastric or duodenal ulcer is no more sensitive to tactile, thermal and chemical stimulation than the intact mucous membrane. This investigator⁷ has more recently described in detail his conception of the mechanism of the pain in peptic ulcer. He first considers duodenal ulcer and attributes the distress to an increase in the intragastric tension of the pyloric vestibule. In brief, he explains the increased tension on the basis of an achalasia or a spasm of the pyloric sphincter interfering with the expression of the gastric contents into the duodenum and the approach of an active peristaltic wave which is sufficiently powerful to obliterate the lumen of the pyloric section. He considers that the mechanism in gastric ulcer is the same as that in duodenal ulcer. In the gastric ulcer located some distance from the pylorus the function of the pyloric sphincter may not be disturbed. In these instances, however, the author points out that a spasm of the circular muscle of the segment of the stomach corresponding to the ulcer may be of sufficient in-

tensity to produce pain when approached by an active peristaltic wave. Ryle⁸ in a consideration of the nature of visceral pain, has stressed the importance of increased tension in the wall of the viscus.

The work of Carlson⁹ on the hunger contraction stimulated an investigation of this feature in connection with the pain of peptic ulcer. Ginsburg, Tumpowsky and Hamburger,¹⁰ Carlson¹¹ and Hardt,^{12, 13} employing the balloon method, observed that the pain in gastric and duodenal ulcer was synchronous with the occurrence of strong contraction waves. These contraction waves corresponded with the hunger contraction waves described by Carlson in the normal individual. These investigators were not able to correlate the appearance of the pain with the gastric acidity. Hardt¹³ reports the study of a patient with gastric ulcer in whom no free acid was demonstrated by repeated aspiration of the gastric contents. In this patient, the typical pain, in almost every instance, occurred with the registration of a peristaltic wave. The results of Ortmayer¹⁴ and Homans¹⁵ neither confirmed nor disproved the above observation. In their work, however, the balloon was probably well above the most active portion of the stomach.

Poulton¹⁶ reports the reproduction of the typical distress in patients with peptic ulcer by the introduction of air into the stomach. Immediate relief was obtained by aspirating the air. In this connection, the observations of MacLeod¹⁷ are of interest. An Esmarch tube was introduced into the first portion of the duodenum in twenty cases of duodenal ulcer. The position

of the tube was verified by fluoroscopic examination. Air was administered and the typical pain reproduced. In each instance, the diagnosis was confirmed by operation. Poulton,¹⁸ later studied visceral pain by means of a balloon in the lower end of the esophagus. He concluded that pain may be induced by increased tone alone, but pointed out that the latter feature was usually accompanied by a hyperperistalsis.

Reynolds and McClure¹⁹ investigated, by fluoroscopic method, the relation of the gastric motor phenomena to the pain of peptic ulcer. They were invariably able to demonstrate these features during periods of distress. A similar method was employed by Wilson²⁰ in the study of the pain of duodenal ulcer. In thirteen of sixteen cases, the pain terminated abruptly upon filling the duodenal cap by manual pressure.

In a previous investigation,²¹ the recurring localized epigastric distress associated with irritable colon and chronic appendicitis was demonstrated to be gastric in origin. This distress, which may have all the characteristic features of that of peptic ulcer, was accompanied by an increase in tone and an active peristalsis of the pyloric section of the stomach. These alterations in the gastric activity were induced by a reflex stimulation from the colon and appendix. They were abolished and the pain eliminated by the administration of atropine.

A reflex stimulation of the stomach from the colon was demonstrated in certain instances of peptic ulcer. This was accompanied by an epigastric distress which was said to be identical

to that attributed to the ulcer. The gastric alterations were similar to those associated with irritable colon and chronic appendicitis, and the pain occurred under the same condition.

The above investigation led to the study of the changes in tone and the peristaltic activity of the pyloric region of the stomach in peptic ulcer. It was believed that a more accurate knowledge of the altered gastric phenomena in this particular section of the stomach would contribute to the explanation of the pain, and possibly point to a more satisfactory method of treatment. The present report is concerned with the mechanism of the pain.

METHOD

The method was similar to that employed in the former investigation. A small rubber balloon was passed into the pyloric section of the stomach and anchored in this location by an Einhorn bucket. This balloon was connected through a water and air system with a bellows tambour which recorded the gastric activity on a kymograph. A Rehfuess tube was usually introduced into the stomach with the balloon and acid determinations made during the registration of the gastric activity.

FINDINGS

The records taken during the active stage of ulcer showed recurring periods of increased gastric activity in which an increase in the tone and spasm of the pyloric section were prominent features. The record in Figure 1 was taken of a patient with gastric ulcer soon after admission to the hospital. Early in the record, there is a violent tone change with the on-

FIG 1

set of an active peristalsis. This was accompanied by the onset of severe epigastric distress and marked rigidity of the upper abdomen. The pain finally became so intense that the operator was alarmed for fear that there might be a perforation. Following the withdrawal of the balloon, however, there was immediate relief from the pain.

The record in Figure 2 represents a continuous registration of the gastric activity of a patient with duodenal ulcer from 9 30 A M to 1 P M. There

were three periods of active peristalsis which were accompanied by a marked increase in tone. Each of these lasted about thirty minutes and two were accompanied by pain. The first occurred between 9 30 and 10 30 A M. It terminated abruptly and the patient went to sleep. He was awakened about 11 A M soon after the onset of the second paroxysm, by a sharp pain. Following the termination of the second period of exaggerated gastric activity, which was similar to the first, the stomach was relatively inactive until

to 30th

about 12 30 P M. when the patient began to feel hungry. The administration of atropine sulphate, 1/50 of a gram, intravenously, was followed by a prompt cessation of the peristalsis, a gradual reduction in the tone and complete relief from the distress for twenty-four hours.

The record in Figure 3 was taken of a patient with gastric ulcer after a few days rest in the hospital. The short paroxysm of increased tone and hyperperistalsis is of interest in that the patient was awakened by pain. This period of increased gastric activity subsided within a few minutes and the patient continued his sleep. The stomach was relatively quiet thereafter until the onset of hunger contractions about noon. While some of the hunger contractions were rather promi-

nent, there was no distress, probably because of the absence of a significant increase in tone.

The findings in Figures 4 and 5 are included because of the similarity in the gastric alteration. It will be observed that each of these records shows two periods of increased gastric activity, accompanied by the typical distress. The second in each instance was precipitated by the introduction of air through a Rehfuß tube. The first paroxysm in Figure 4 terminated spontaneously. The others, in the order of their occurrence, subsided following the aspiration of air, belching and vomiting. These observations seem to indicate that the introduction of air is an effective means of stimulating the stomach. Furthermore, this induced stimulation may be suddenly

FIG 3

FIG 4

istalsis intensified the distress. It is assumed that the sudden termination resulted from the escape of gas through the relaxation of the pyloric sphincter by the atropine.

COMMENT

In the above series of experiments, the gastric alterations were similar during periods of pain. These changes were characterized by an increase in tone and the onset of an active peristalsis. The pain in each instance corresponded with the passage of a peristaltic wave except in the more severe form when there was an apparent persistent spasm of the pylorus (Figure 1). These findings are in accord with the observations of Ginsburg, Tumpowsky and Hamburger, Carlson and Hardt. While a hyperperistalsis invariably accompanied a significant increase in tone, the latter feature was apparently fundamental to the production of the pain. It will be noted that the terminations of the paroxysm of increased gastric activity were likewise similar, regardless of the agent responsible. In some instances, the termination was spontaneous, while in others, it promptly followed belching, vomiting, the aspiration of air, or the administration of atropine. These observations support the contention of Hurst and Ryle, that the pain is primarily dependent on an increase in the intragastric tension. The roentgenological findings of Wilson, in the study of the pain of duodenal ulcer may be explained on this basis. It will be recalled that the pain terminated abruptly upon filling the duodenal cap by manual pressure. It might thus be argued that the pain was relieved by the re-

duction in the intragastric tension from expressing the gastric contents into the duodenum.

The significance of the observation of Poulton on the occurrence of typical ulcer pain following the introduction of air into the stomach is more apparent in view of our results. In the experiments in Figures 4 and 5, the paroxysms of increased gastric activity accompanied by pain were induced by the administration of air and terminated by the reduction in the intragastric tension. The experiment in Figure 6 is of particular interest in this connection. It would seem probable that the gas formed from the administration of the sodium bicarbonate was responsible for the increased gastric activity.

CONCLUSIONS

These findings are very similar to the gastric alteration associated with irritable colon and chronic appendicitis, and the pain occurred under the same condition. In the former study, it was not believed that the hydrochloric acid of the gastric contents was a factor in the production of the distress, and in the present investigation, there was no apparent correlation in these features. The pain in each may be relieved by various agents as alkalis, food, belching, aspiration of air, vomiting and the administration of atropine. It would thus seem that the production of the pain is primarily dependent on the altered motor phenomena and the associated increased gastric tension. We wish, however, to investigate other measures commonly employed in the treatment of the pain of peptic ulcer before coming to a more

definite conclusion At the same time, the influence of the administration of a more detailed study will be made of hydrochloric acid.

Rheumatoid Arthritis*

By RUSSELL L. CECIL, M D , *New York City*

RHEUMATOID arthritis might well be called the step-child of Medicine for the reason that, like some other chronic diseases, it has always received scant attention from both investigators and practitioners. Osler himself is quoted as having remarked that when an arthritic patient walked into his consultation room, he always had a strong inclination to jump out the window. Most of the research work on arthritis has been spasmodic or accidental, and until recent times few practitioners have made a special study of the disease.

It is unfortunate that such a common malady should have received this neglect. Within the last few years, however, a noticeable change has taken place in the attitude of medical men toward rheumatic diseases, and because of this intensive study and research, definite knowledge is being gained concerning the various types of arthritis and the modes of treatment. For one thing we have learned to classify arthritic conditions into various groups. Both European and American students are agreed that most cases fall into one or the other of two main divisions, infectious or rheumatoid arthritis, and hypertrophic or osteoarthritis.

Osteoarthritis is something that all

of us achieve as the reward of old age, though it may appear in the early fifties, particularly in stout women who have just passed through menopause. There is no reason to believe that osteoarthritis is an infection, on the contrary, it appears to be a phase of senescence brought about by insufficient blood supply to the joint structures. The small capillaries become thickened and occluded, and as a result certain degenerative changes occur in the bone and cartilage. A classic example of osteoarthritis is furnished by the so-called Heberden's nodes on the distal phalangeal joints of the fingers.

Rheumatoid arthritis is a true inflammatory process characterized in the early stages by migratory pain and swelling in various joints and in the late stages by ankylosis and deformity. For twenty years rheumatoid arthritis has been looked upon by most students of the disease as a chronic infection, though the exact nature of the infection has not been disclosed. There are several features of the disease which strongly support the infectious theory: its almost constant association with foci of infection, the moderate fever and leukocytosis which occur in some cases, the loss of weight and secondary anemia, the complications such as iritis, pleuritis and pericarditis, and finally its similarity in the early stages to gonococcal arthritis and rheumatic fe-

*Presented before the Baltimore Meeting of The American College of Physicians, March 23rd, 1931

ver all suggest an infectious origin. The pathological findings are also those of a chronic infection. The granulation tissue which develops in the joint cavity and which if not checked, eventually fuses the articular surfaces together, can hardly be imagined as being derived from any other source than a bacterial one. The adhesions which one sees in these joints differ in no respect from the adhesions in the peritoneal and pleural cavities resulting from bacterial infection.

Bacteriologists have made extensive efforts to solve the riddle of rheumatoid arthritis, but their results have been inconsistent and desultory. To be sure, some form of streptococcus has long been suspected of being the etiological agent, chiefly because streptococci are frequently present in the original foci of infection, but efforts to isolate streptococci from the blood and joints have been either entirely unsuccessful or only partially so.

Moon and Edwards,¹ Richards,² Billings³ and his co-workers, and Hadjopoulos and Burbank⁴ have all reported the isolation of streptococci from the blood or joints or from both sources in a certain number of cases of rheumatoid arthritis, the percentage of positive cultures, however, being comparatively small. More recently Forkner, Shands and Poston⁵ have reported cultures from the joints in 63 cases of chronic infectious arthritis with the isolation of streptococci in 11, or 17 per cent. of the cases. In a series of papers published during the last two years from the medical department of Cornell University, the writer, in collaboration with Edith E. Nicholls and Wendell J. Stainsby,^{6,7}

has described a method of culturing the blood and joints in rheumatoid arthritis and also in rheumatic fever, which has proven remarkably satisfactory in respect to the isolation of streptococci. The basis for successful cultivation of these streptococci appears to rest, first, on very carefully and specially prepared culture media, and second, on observation of these cultures over a period of two to four weeks of incubation. Altogether 154 cases of rheumatoid arthritis have been subjected to blood cultures by this method. Of these cases 49 were also subjected to joint cultures. Of the 154 patients who had blood cultures, 96 or 62.3 per cent, yielded a streptococcus. In several patients a streptococcus was obtained from the blood in two or even three successive cultures.

As a control on these findings, 104 individuals either normal or suffering from some condition other than rheumatoid arthritis, were subjected to blood cultures, the technic being similar in all respects to that used on patients with rheumatoid arthritis. Of these controls 20 were normal healthy individuals with no joint symptoms and no obvious foci of infection. The remainder of the control group were patients suffering from some disease. Of these 23 were middle-aged patients, who presented a typical picture of degenerative arthritis with hypertrophic changes in the bones. The blood cultures on all this group were sterile. The remaining 61 controls were patients suffering from various diseases, including infections of various kinds. Of these 61 patients, 4 showed streptococcus viridans in their blood cultures. The four positive controls pre-

sented certain features in common, three had active foci of infection of the type usually associated with arthritis, while the fourth was an acute respiratory infection. In this connection it is interesting to note that there have been several reports in the literature lately on isolation of streptococci from the bloodstream of patients with acute respiratory infections.

In 40 cases of rheumatoid arthritis cultures were made from one of the affected joints. In 33 cases (67.3 per cent) a short-chained streptococcus was recovered from the joint cultures. In 48 cases that were subjected to both blood cultures and joint cultures, 37 (77 per cent) showed a streptococcus in either the blood or the affected joint. Control joint cultures were made on 18 patients who were suffering from conditions other than rheumatoid arthritis. The joint cultures from these 18 controls all remained sterile.

Time does not permit a detailed description of these streptococci which have been recovered from the blood and joints of rheumatoid patients. Suffice to say that both cultural and immunological evidence supports the conclusion that they are atypical hemolytic streptococci. They possess a remarkable capacity, however, for losing their hemolytic quality when kept for some time on laboratory culture media. They are quite different in their cultural and biological characteristics from the streptococci which we recover from the blood and joints of patients with rheumatic fever. In the latter disease cultures have usually yielded green streptococci, which tend to fall into a number of biological groups.

Even more significant perhaps than the presence of streptococci in the

blood of rheumatoid patients are the specific streptococcal agglutinins which these patients show in their blood sera. These agglutinins have been recently described in a publication from our clinic, and their presence has already been corroborated by Dawson, Olmstead and Boots⁸ who, because of these agglutinins, advance the theory that rheumatoid arthritis is a streptococcus hemolyticus infection. They look upon the joint manifestations, however, as allergic or toxic in character. These streptococcal agglutinins are so definite in a high percentage of cases that they can be made of considerable practical value in the diagnosis of this form of arthritis. In perfectly typical cases, such a test is perhaps not necessary except where the titer of the agglutinins is to be followed as an index of treatment, but in very early cases or in mixed forms of arthritis, or particularly in obscure back conditions, the agglutination test has proved of great value in our arthritis clinic in the correct classification of cases. In routine clinic work we have largely abandoned blood and joint cultures because they are difficult and time-consuming, and prefer the agglutination reaction both for diagnosis and prognosis. As a rule the more advanced the arthritis, the more potent the agglutination reaction. The agglutinin titer in rheumatoid arthritis usually runs between 1:320 and 1:5120 or even higher. Every patient with arthritis now admitted to the Cornell Arthritis Clinic is subjected to an agglutination test and a sedimentation test. Both of these tests are extremely valuable in differential diagnosis and both are of value in guidance of therapy.

When arthritic strains of streptococci are injected intravenously into rabbits, a faithful reproduction of rheumatoid arthritis is produced in these animals. Streptococci are recovered from the blood and joints of the arthritic rabbits and their blood contains agglutinins similar in all respects to the agglutinins found in the blood of human patients. The problem of reproducing rheumatoid arthritis in animals is a large one and so far only the surface has been scratched in our work at Cornell. We hope to go into this problem more thoroughly in the future.

It is only fair in this connection to report that the results obtained from bacteriological study of rheumatoid arthritis in other clinics have not always been consistent with our own. Nye and Waxelbaum⁹ were unable to corroborate our results in either rheumatic fever or rheumatoid arthritis. Dawson, Olmstead and Boots¹⁰ have obtained only negative results from blood and joint cultures in rheumatoid arthritis. Margolis and Dorsey¹¹ of the Mayo Clinic have partially corroborated our findings in that in a total of 29 specimens of either bone or synovial membrane from patients with infectious arthritis, 6 yielded streptococci on culture, and 5 diphtheroid bacilli. The most complete corroboration of our findings has come from Gray and Gowen,¹² who have recently published their results on blood and joint cultures in rheumatoid arthritis. In a series of 37 cases of rheumatoid arthritis, a streptococcus of the arthritic type was recovered in 67.6 per cent of the cases, a proportion almost identical with that obtained by us. Gray and Gowen have also noted that the organism produced

partial hemolysis on blood agar. Swift¹³ at the Rockefeller Institute obtained streptococci in only a small percentage of his patients with rheumatic fever, but Dr. William H. Park¹⁴ and his co-workers in the research laboratories of the New York City Department of Health are recovering green streptococci from both the blood and joints in a very high percentage of rheumatic fever cases.

This inconsistency in results is of course disappointing, but I believe can be explained on the basis of some slight differences in culture media. That such differences do exist is proved by the fact that even when cultures of our streptococci are sent to some laboratories, the local bacteriologist is at times unable to cultivate the organism on his own culture media.

Some investigators who have not been successful in cultivating streptococci from the blood and joints of patients with rheumatoid arthritis and rheumatic fever have advanced the theory that the streptococci which we have recovered are not actually in the blood or joints, but are contaminations from the skin or air. This theory, however, is hardly valid because

- 1 Streptococci are rarely encountered as contaminants in bacteriologic work. In our own laboratory we have repeatedly exposed plates for several hours at a time, but have never recovered streptococci from them.

- 2 If these streptococci were contaminants one would expect to find just as high an incidence of positive cultures in the controls as in the arthritic series. Such, however, was not the case.

- 3 In almost 50 per cent of the positive cultures, both blood culture flasks

yielded streptococci, a finding entirely inconsistent with the contamination theory.

4 The high titer of specific streptococcal agglutinins in the blood and joint fluids of arthritic patients speaks strongly for the presence of these streptococci in the tissues themselves and also for their pathogenic quality. The fact that the agglutinins tend to disappear as the patient recovers is also significant.

Perhaps the most important practical phase of the newer bacteriology of rheumatoid arthritis is its bearing on vaccine therapy. Vaccine therapy has no doubt been considerably abused in some quarters, and for this reason has come into disfavor with many physicians as a therapeutic agent. This applies to arthritis as well as to other acute and chronic infections. However, in allergic conditions such as bacterial asthma and certain skin conditions, vaccines have come to be a part of the standard treatment, and recently Swift has published favorable reports on the use of streptococcus vaccine in the treatment of rheumatic fever, in which allergy seems to play an important part.

We have presented evidence to show that rheumatoid arthritis is a chronic specific infection caused by a special strain of streptococcus hemolyticus. If further study confirms this theory, it is most natural that efforts toward the development of some form of specific therapy should be undertaken with this organism. During the past three years we have treated several hundred rheumatoid patients with a streptococcus vaccine prepared from our "typical strain." We hope some time in the near future to report in detail our

results with this form of therapy. At present I can do no more than give the impressions obtained from three years of experience with this agent. The vaccine was originally prepared in the usual manner, that is, by killing washed cultures at 60° C and standardizing by the Wright method. More recently, however, the streptococci have been killed by formalin instead of by heat, and this method seems to have produced a vaccine of higher antigenic power. At present we are administering vaccine by both the subcutaneous and intravenous methods using doses of from 100,000,000 to 1,000,000,000 in the former, and from 100,000 to 1,000,000 in the latter. In both methods we try to avoid unpleasant reactions. The interval between injections is four to five days, occasionally a week. In trying to evaluate vaccine therapy in arthritis, one must take into consideration the part which improved personal hygiene and the removal of any foci of infection may play in a patient's recovery. Other forms of therapy, such as medication, physiotherapy, hydrotherapy, etc., must also be given some weight, but unfortunately, in our experience, this is not considerable.

The results which we have obtained with vaccine therapy in the treatment of rheumatoid arthritis may be divided roughly into three groups. 1 Patients who make complete recovery from all joint symptoms. These patients for the most part have had a mild form of arthritis, but some could be classified as moderately severe. 2 Patients who make considerable improvement, but eventually reach a stationary stage and do not recover completely. These are

usually patients who have had arthritis for several years, with well-marked joint symptoms 3 Patients who show little or no effect from vaccine therapy These are usually patients of long-standing, with well-marked or advanced joint symptoms There are exceptions to all these groups I can recall some early cases that have not responded to vaccine therapy, but on the other hand I can recall some almost hopeless patients who have made surprising improvement with practically no other treatment than rest and vaccine In each of the three groups there have been many patients who, in addition to the vaccine treatment,

have had foci of infection removed; but there are many others whose treatment consisted of vaccines alone

On the whole, we may say that after having started out with considerable misgivings as to the value of streptococcus vaccine in the treatment of this disease, we have been forced to take the opposite position, and we now consider streptococcus vaccine an important therapeutic agent in the treatment of rheumatoid arthritis Just how much of the benefit obtained is referable to specific effect and how much to foreign protein effect is a problem which can be settled only by further study

A Diagnostic Triad in Syphilitic Aortitis*†

By C S DANZER, M D , F A C P , Brooklyn, N Y

IT is superfluous to discuss the importance of recognizing aortic syphilis early. The contrasting results in properly treated and untreated cases speak for themselves. As far as I know, a clean-cut symptom-picture by which this disease may be diagnosed, is still lacking. I shall attempt this task in the present communication.

The confusion in the past was due largely to two factors, the frequent association of this disease with aortic atherosclerosis, and the misinterpretation of the Wassermann reaction.

How often have we seen on examining an aorta at autopsy, atheromatous, calcified plaques with wrinkling of the intima and pink streaks in the depressions between the folds! The commonly accepted diagnostic criteria, consisting of a dilated aorta, a systolic aortic murmur and a ringing aortic second sound are frequently due to co-existing aortic sclerosis with or without hypertension, rather than aortic syphilis. I have observed narrow or normal aortas without the signs just enumerated, in well-defined syphilitic

mesaortitis, as the following case will show.

G H, a 40 year old male, who denied venereal infection, consulted me on February 28, 1929, because of severe *angina* after effort, excitement or meals, during the past year. It was especially severe in cold weather or when his stomach was full. He had observed that eating rare beef was apt to be followed by anginal pains. In the past 6 months he experienced abdominal pain and bloating after meals and excessive flatus. When the latter was expelled, the *angina* lessened. He slept badly because of exciting dreams which in turn induced *angina*, dyspnea and an indescribable "fright" over the precordium. These exhausted him, so that he had to get out of bed and stand in order to relieve the *angina*. Digitalis aggravated the *angina*.

Physical examination was essentially negative, no aortic murmurs, nor accentuation of the A₂ over the aorta. Only in the supra-clavicular fossa (over the subclavian artery) was the A₂ intensified. B P 110/60, pulse varied from 54 to 64 and the heart sounds were feeble. E K G Diphasic T in lead I. *The width of the aorta was normal on x-ray* (6 ft plate). Only a slight knuckling on the left border could be seen. The blood Wassermans done with the usual technique using both alcohol and cholesterol antigens and the Kolmer modification were strongly positive, the Kahn test reacted similarly.

The other significant features in this case were the negative vagus (carotid sinus) reflex and the increased blood sedimentation reaction. These points will be elaborated later. Suffice it here to say that

The carotid sinus reflex was negative on the left side and doubtful on the right

*From the Medical Services of the Cumberland and Unity Hospitals, Brooklyn, N Y

CAROTID SINUS REFLEX

Pulse Beats per 10 second Period

	Right side	Left side
Before test	10	10
During test	8	10
After test	10	10

The blood sedimentation reaction with the Westergren method was 41 mm per hour (normal 4-6 mm) and 106 for 24 hours (normal 40-60) After 8½ months of treatment (bismuth, mercury, salvarsan, iodides) the sedimentation rate was reduced to 6 mm per hour and 68 mm per 24 hours The Wassermann tests still showed a 3 plus reaction, but after a course of bismarsen, the Wassermann and Kahn tests became negative and all the clinical symptoms disappeared (October 1, 1930)

The Wassermann has at times misled me False positive reactions, especially with cholesterol antigens, are not rare in cases of aortic atheromatosis In such cases, a wide aorta, a bruit, or ringing A2 sound may easily be ascribed to luetic aortitis The conversion of a positive into a negative complement-fixation test after provocative salvarsan injections, the correlation with other serological reactions (Kolmer method, alcoholic antigen, and Kahn test) will reduce this source of error The following case will illustrate the point under discussion

A S (case No 236403), a man, 59 years old, came to the Medical Center complaining of recurrent anginal pains on exertion or after eating He got no relief from nitroglycerin Three months before he developed symptoms of acute obstruction of the left coronary artery This was verified by the existence of a negative T wave in lead I and a notched R in all the leads of the electrocardiogram X-ray disclosed calcification and knobbing of the aorta, and moderate cardiac (especially left ventricular) enlargement The cardiothoracic ratio was 54% The B P was low 104/70, and the heart sounds were audible Blood Wassermann on

December 11, 1929, showed a 3 plus reaction with the cholesterol antigen, negative with the alcoholic The same result was obtained on repetition of the tests a week later He was given 2 doses of neo-salvarsan (3 Gm) a week apart On January 14 and 20 the Wassermann tests with both antigens gave a negative reaction The Kahn test was also negative This man was obviously suffering from coronary and aortic sclerosis, not due to syphilis

On the other hand a person with a negative Wassermann and none of the conventional signs of aortic disease may have aortic lues In such instances, repetition of the blood examination after provocative measures, spinal fluid examination, the therapeutic test and the clinical picture to be described in this paper, will generally settle the diagnosis

T D, (case No 240534), an obese, ruddy, 65 year old man came to the Medical Center on January 16, 1930, complaining of anginal pain on exertion or after meals for the past 12 years Of late these had become quite severe and at times were accompanied by typical "angor mortis" He had a wide tortuous aorta, 65 cm in diameter, moderate inaudible heart sounds with negative T waves in all leads of E K G, small pupils which reacted to light, normal tendon reflexes, and a negative Wassermann with both alcoholic extract and cholesterol antigens Thirty-five years ago he had a chancre which was untreated Despite the results of the Wassermann test, it seemed plausible that the man had latent syphilis with localization in the aorta With this thought in mind, the patient was given a course of iodides The Wassermann reaction (end of March, 1930) gave a 2 plus reaction with an alcoholic antigen

Syphilitic mesoaortitis has in many cases a characteristic symptom triad consisting of angina pectoris, a negative carotid sinus reflex, and a rapid blood sedimentation rate A positive

Wassermann occurs in two-thirds of the cases of luetic aortitis and serves only as a confirmatory test. Dilatation of the aorta, insufficiency of the aortic valve, a murmur and a ringing A2 sound may, but need not, be present. It is most commonly a disease of the fifth decade of life. The following two cases are presented in order to emphasize the diagnostic triad.

K R, a woman 45 years old, who had never born children but had one miscarriage, came on May 1, 1929, complaining of burning anginal pain during the past year. It radiated down the arms and to the teeth and came on especially on walking out of doors, uphill, or during cold weather. When she leaned forward, she experienced more pain in the sternum. The chest pain was compared to that of swallowing a hot potato. She had no knowledge of a luetic infection. A diagnosis of hypertension was made a year before.

The patient was obese (about 50 lbs overweight) with a Corrigan pulse, 64 per minute, B P 185/70, hemoglobin 57 per cent and a normal urine. Over the cardiac base a to-and-fro murmur was heard, and the diastolic bruit was transmitted to the apex. The aorta was wide, and dynamic pulsations were seen on the fluoroscopic screen. The E K G showed a left ventricular preponderance with no T wave changes.

The carotid sinus reflex was negative on both sides.

CAROTID SINUS REFLEX		
Pulse Beats per 10 second Period		
	Right side	Left side
Before test	11	11
During test	11	10
After test	11	11

The sedimentation rate was 53 mm per hour, 124 mm in 24 hours.

The Wassermann showed a 4 plus reaction with the various antigens and Kolmer technique.

Diagnosis *Luetic mesoaortitis complicated by aortic insufficiency.*

E B, a 36 year old police officer, experienced for 1½ years angina on exertion or after meals. Amyl nitrite gave him immediate relief. His angina increased steadily despite the reduction of weight from 225 to 185, brought on by dieting. Examination of his heart disclosed a loud rasping diastolic murmur over the entire precordium with a heaving apex beat. He had no edema of the legs. The B P was 105/60. The aorta was dark, wide and expansile and the left ventricle was markedly hypertrophied. The blood Wassermann was 4 plus. He was given 6 doses of salvarsan by his physician, Dr G, but developed chills and a temperature of 104° following the injections, so that they had to be discontinued.

Carotid sinus reflex was essentially negative.

CAROTID SINUS REFLEX		
Pulse Beats per 10 second Period		
	Right side	Left side
Before test	22	23
During test	20	20
After test	22	22

A diagnosis of *syphilitic mesoaortitis with aortic insufficiency* was made and bismuth injections and iodides were advised. He improved remarkably for a while, attempted to perform the strenuous duties of his calling and the angina returned. He then consumed 135 tablets of nitroglycerin (gr 1/100) daily for 2 weeks, developed progressive heart failure and died.

A leading symptom of this disease is angina pectoris. The pain may be very severe especially in an hypersensitive person or absent in one insensitive to visceral pain. Between these extremes there are numerous transitional variations. The conventional steno-cardiac pain after exertion or eating is by no means invariable. It frequently comes at rest, during the night and, as I have observed rather frequently on bending forward.

The degree of response to painful stimuli may be roughly tested by ap-

plying deep pressure with the thumb to the styloid process (between the mastoid and the mandibular angle), a method introduced by E. Libman of New York. It should be done carefully by exerting equal pressure on both sides

A hypersensitive person says "it hurts," and draws the head away, the normal one says "it is just the pressure of your fingers", a hyposensitive individual says nothing when the test is made

If pressure against the styloid of one side is more painful, the anginal pain is usually felt on the homolateral side. In such cases pressure over the brachial plexus (Schmidt) or the eye (Bernstein) may also be more painful on the affected side.

In a hyposensitive person, anginal equivalents must be diligently looked for. These commonly consist of disagreeable sensations in the chest varying from anxiety to a premonition of impending death, usually though by no means always, after exertion. Sometimes the sensation is not even projected to the chest. It may consist of an unexplainable "feeling of nervousness."

As a general proposition one may expect to find a typical reaction when a normal or hypersensitive person develops aortic disease. This rule is not invariable as the next case will show.

I. K., a 47 year old, highly emotional Jew with a metabolic rate of plus 12 and bilateral hyperesthesia of the styloids and ocular bulbs, but no brachial hyperesthesia, developed progressively increasing palpitation on exertion, nocturnal attacks of asthma and nocturnal fits years ago. Several weeks before examination he suffered a severe attack of vertigo and vascular collapse. His

physician, Dr. S., found him with a cold clammy skin and later the systolic B. P. was 210. Ever since then his chief trouble has been palpitation on exertion, *paroxysms of nocturnal dyspnea and heaviness in the chest, but without acute pain*. After careful questioning he admits only one attack of pain in the precordium and left arm.

Examination. He had a dark, wide aorta and a slightly enlarged heart on x-ray. A delayed systolic murmur, a loud A₂ over the aorta and a short systolic blow at the apex were heard. B. P. 183/105. *Carotid sinus reflex was strongly positive*, especially on the right side.

CAROTID SINUS REFLEX

Before test	20	19
During test	14	16
After test	20	19

On February 20 a soft diastolic puff was heard to the inner side of the apex. Was this an aortic insufficiency? If so it would argue strongly for the luetic origin of the angina. A blood sedimentation reaction was done and found decreased (3½ mm per hour, 60 mm in 24 hours) and the carotid sinus reflex was positive. This eliminated, to my mind, the diagnosis of syphilitic aortitis, though his age was 47. The Wassermann on Feb. 21 was negative and supported the diagnosis of aortic sclerosis.

This case illustrates the existence of coronary (aortic) disease in a nervous hypersensitive man, which induced, instead of anginal pain, palpitation on exertion and cardiac asthma. The absence of pain in coronary disease in a hypersensitive individual is perhaps the exception to the rule.

Alarming dreams may arouse the patient from sleep with a frightful but not painful precordial sensation and constitute another variation of the anginal symptom (L. Braun¹).

A hyposensitive person may have extensive coronary disease, even a fa-

tal coronary thrombosis without pain. In this category is the sudden and unexpected death after a formal dinner casually ascribed to "acute indigestion", or the apparently healthy man who is found dead in bed in the morning, or the painless death during sexual intercourse (*la morte douce*). People with reduced sensibility to pain are likewise apt to be the carriers of painless duodenal ulcers for years. Amidst good health a peritoneal perforation or a severe hemorrhage discloses the presence of the treacherous lesion.

It behooves us, therefore, in hyp-sensitive people, to regard minor chest symptoms or simple indigestion seriously and to look for organic disease in the heart or abdomen. It is plain that the estimation of the reaction to pain should be frequently practiced.

The next sign in the triad which merits discussion, is the negative "carotid sinus reflex" (Hering). At the Boston meeting of the American College of Physicians in April, 1929, I² reported the occurrence of a positive reaction in non-syphilitic coronary angina. The case L. K., just described, illustrates this point. In luetic aortitis with angina on the other hand, the reflex is generally negative. In order to clarify these remarks it will be necessary to review briefly the physiology and clinical application of this reflex.

It is elicited by pressing the thumb over the common carotid artery at the level of the thyroid cartilage. At this point the vessel bifurcates into its internal and external branches and a slight bulging of the artery called "carotid sinus" may be felt. The heart rate is counted for 10 seconds, then the sinus is compressed against the

firm tissues of the neck for 10 seconds and the cardiac frequency is again determined. Similar counts are made for the following two 10 second periods. The reflex is positive if there is a distinct slowing during the carotid compression.

This is the old vagus pressure phenomenon described by Czermak,³ who thought it due to the mechanical stimulation of the efferent vagus fibers in the carotid sheath. His error has been pointed out by Hering⁴ who showed that even pinching the exposed vagus nerve, fails to slow the heart. On the other hand, light pressure with the finger on the skin over the carotid, a manipulation obviously insufficient to reach the deep position of the vagus, may cause cardiac standstill for 5 to 7

Fig 1

seconds I have observed such reactions many times

Hering proved that the afferent part of the reflex arc was formed by the so-called carotid sinus nerve, a small branch of the glosso-pharyngeal. The motor vagus fibers form the efferent segment of the arc. The reflex therefore starts from the carotid sinus and ends in the heart. The common nucleus of the 9th and 10th cranial nerves completes the arc.

Last year I suggested as a possible explanation for a positive reflex² an arteriosclerotic lesion at the carotid sinus. It has been shown by Chiari⁵ that this lesion occurs frequently in association with coronary arteriosclerosis. Monckeberg⁶ confirmed his findings and said that these lesions are the earliest localizations of the arteriosclerotic process and occur often in young adults or even children. Thus the reason for a positive vagus response in cases of coronary (and carotid sinus) sclerosis is evident.

The importance of applying this test to young people even without angina is obvious. In a recent address by Joslin⁷ the existence of premature and serious arterial disease (coronary sclerosis) in youthful diabetics was stressed. This is but one instance where the test may be applied to advantage.

A little light on the otherwise obscure pathogenesis of juvenile arteriosclerosis was furnished by the work of E. Wolfkoff⁸ who found nodular thickenings of the intima in the coronaries beginning in infancy. These, of course, are physiological reactions. In young adults (32-36 years) the thickness of the intima exceeds by several times

that of the media, especially near the origin of these vessels. The superimposition of atheromatous lesions on a partially stenosed coronary, might seriously interfere with the myocardial circulation and offer an explanation for the frequency of the symptoms of coronary obstruction even in young people.

The following case may illustrate how the carotid sinus reflex may help to recognize pathology in the coronary arteries before the onset of angina or other clinical symptoms.

C. R., a 57 year old, healthy-looking business man consulted me because of generalized pruritus for 3 to 4 weeks especially on coming from a cold into a warm room. He noticed that the palms of his hands perspired freely. Thirteen years ago he suffered from pruritus which recurred during the following 3 winters. He had no precordial pain nor dyspnea, and his B. P. was 145/85. His urine was negative until recently when a trace of albumin and a few hyaline and granular casts were found. The physical examination was essentially negative, except for a slightly ringing A₂ sound. The aorta under the fluoroscope was not dilated, but dark, the cardiac size was normal. Capillaroscopy showed a group of aneurismal and varicose capillaries in the skin near the nail-beds. Incidentally this was the anatomical substratum for his pruritus (cutaneous vasoneurosis). The blood sedimentation reaction was moderately increased.

CAROTID SINUS REFLEX

Pulse Beats per 10 second Period

	Right side	Left side
Before test	10	10
During test	5	10
After test	10	10

Positive reaction on right side

The presence of a positive carotid sinus reflex pointed to a sclerotic lesion of the right carotid and coronary arteries. The dark aorta and the ringing

A2 sound supported this diagnosis. This man had at the time of examination no cardiac symptoms, but on further inquiry, it was learned that he was rejected by an insurance company 11 years ago (age 46) for albuminuria and hypertension. Eight months after that, he was operated upon for a perinephric abscess, and 1½ years later his urine and blood pressure were found normal and he was accepted by the insurance company.

The positive carotid sinus reflex was the most significant sign of arteriosclerosis and dovetailed with the history of hypertension 11 years ago. He is probably in the *presymptomatic stage of coronary disease* at present. Further observation will be necessary in order to verify this hypothesis.

A positive carotid sinus reflex may therefore indicate coronary arteriosclerosis even before or without angina. Timely care of the heart and vessels may aid in prolonging life. In the case of *aortic syphilis*, this reflex is generally negative, carotid pressure fails to produce cardiac slowing. The reason for the negative reaction may be as follows. Syphilitic aortitis is generally unassociated with coronary closure or lesions at the carotid sinus unless complicated by atherosclerosis. Since such lesions are required to give a positive vagus reaction, its absence in aortic lues may be understood.

The third symptom is the rapid blood sedimentation rate. How can we explain this? It must be recalled that *syphilitic aortitis is an infectious process, aortic sclerosis is a degenerative one*. A fast sedimentation rate occurs chiefly in infectious conditions. It is however non-specific, occurs in

active infections, and is comparable to an increased leucocyte count. This test has been successfully used in following the progress of such infections as pulmonary tuberculosis, pelvic inflammations and syphilis. Active aortic lues is associated with a *fast sedimentation rate because it is an inflammatory disease*. Up to the writing of this paper, I have seen no case of active syphilitic aortitis without a rapid sedimentation reaction. For the performance of this test, the Westergren⁹ technique is recommended because of its simplicity.

The following case will serve to illustrate the error that may result from the misapplication of the carotid sinus and sedimentation reactions. In this patient, the *failure to sufficiently relax* the muscles of the neck to effectively compress the carotid artery, resulted in a negative response. At a later examination the patient relaxed better and a positive reaction was elicited on the right side. Another confusing feature in this patient was the fast sedimentation rate which was thought at first to indicate an active infection, perhaps syphilis. It was later accounted for by myocardial necrosis following coronary thrombosis. The latter condition, in my experience, is often the cause of rapid blood sedimentation. It is necessary, therefore, to insist upon the entire symptom triad for the diagnosis of syphilitic aortitis.

Case W J Y, 59 years old, suffered for the past 3 years from angina pectoris on exertion, particularly in cold weather or on walking against the wind. Postural dizziness, brachial paresthesia, anginal pain in the left arm, ear, face, and dyspnea on effort completed the picture. In the past year his symptoms had been quite severe,

though never as bad as during the month before examination. Since then he had been home and mostly in bed. The examination disclosed a muddy pallor of the face, the pupils reacted to light, the blood pressure was 135/85, sensibility to pain over the styloid was normal, the heart sounds were feeble and slightly irregular, the liver edge was a hand's breadth below the costal margin and over the left pulmonary base a number of râles were heard. He had no edema of the legs. The aorta was wide and the cardiac outline hazy on fluoroscopic examination. The lungs showed congestive hyperemia. Urine was negative except for a moderate increase in urobilinogen due to liver congestion.

The blood sedimentation reaction on two occasions gave a very fast rate, the first reading was 83 mm per hour, the next one 95 mm.

The carotid sinus reflex at the initial examination gave a negative response. It seemed at first that with a fast sedimentation rate, it might indicate syphilitic aortitis. On the second examination, however, though the blood sedimentation was still fast, the *carotid reflex* was distinctly *positive* on the right side, so that for 4 seconds, there was *complete cardiac standstill*.

We still had to explain the fast sedimentation. An electrocardiogram showed a negative or diaphasic T wave in leads 1 and 2 with a convexity of the ST interval, indicating a myocardial lesion of coronary obstruction. It was obvious, therefore, that the patient was undergoing myocardial necrosis which accelerated the blood sedimentation. Negative Wassermanns with the different antigens and techniques excluded the diagnosis of syphilis.

The sedimentation test is extremely valuable when used judiciously. It can, however, be very misleading as the following case will show.

H. G., male 58, consulted me on Sept 29, 1927, because of a vise-like constricting pain in the chest and abdomen after exertion in the past 8 days. Dyspnea was not present. Abdominal distension after meals and

nocturia had been present for 6 months. He was rejected by a life insurance company 6 months previously because of glycosuria.

He was a little man (Wt 109 lbs) with a grayish complexion and a B P 115/70, and his urine had only a trace of albumin. Eyes showed no arcus senilis. Heart. An irregularly intermittent rough systolic and a short diastolic murmur were heard over the entire precordium. On fluoroscopy a dilated aorta with a hypertrophic left ventricle were seen. There was no fever. A pericarditis was present, but its etiology was obscure. Was it rheumatic or epistemonocardiac?

Two years later he returned with entirely different complaints. He had lost 15 lbs, felt weak, had a dragging sensation in the lower abdomen and dyspnea on exertion. His B P was 95/60, his hemoglobin 56 per cent and his stomach contents showed a subacidity. *His blood sedimentation was very fast*, 56 mm per hour and 127 mm in 24 hours. *Carotid sinus reflex was moderately positive on both sides*.

CAROTID SINUS REFLEX

Pulse Beats per 10 second Period	Right side Left side	
Before test	10	9
During test	7	6
After test	10	9

In view of the fast sedimentation reaction with angina the question of aortic syphilis arose. This diagnosis was excluded because the carotid reflex was positive and the Wassermann was negative. The diagnosis of coronary sclerosis is more likely and his pericarditis of two years ago was perhaps due to myocardial infarction.

To account for his sedimentation reaction one must assume either another infection or gastric subacidity. I have found the blood sedimentation increased in several cases of gastric subacidity. I fail to understand the reason, but offer it simply as an empiric

observation In this case, therefore, the subacidity of the stomach may stand in some relationship with the fast sedimentation

This case illustrates also the possibility of detecting coronary disease in the absence of anginal or other cardiac symptoms The loss of weight with its consequent reduction of the load on the heart, may be responsible for the disappearance of the anginal symptoms

With the help of the carotid sinus reflex, latent coronary disease may be recognized, even those who lose their stenocardiac symptoms, e g, with the advent of cancerous or other forms of cachexia, may be diagnosed

We must insist therefore, that the "symptom triad" be used collectively, not singly A fast sedimentation reaction alone may be caused by infections, gastric anacidity, or myocardial necrosis

Mrs M J, 65, with a history of rheumatic endocarditis in her son and grandchildren, had been complaining in the past 15 months, of attacks of palpitation and throbbing in the head These started suddenly and ended more gradually They came frequently during the night and awakened her from sleep She also experienced palpitation and cold sweats on exertion but no dyspnea The first attacks came after an emotional bout The paroxysms of tachycardia kept the patient from sleeping The essential features in her examination were a markedly dilated aorta on fluoroscopic examination, moderate hypertension, 185/85, slight bilateral arcus senilis, pupils reacted to light, a loud diastolic decrescendo murmur over the entire precordium, and a short systolic murmur over the aorta The fingers showed a positive capillary pulse There was neither edema of the legs, nor congestion of the liver or lungs The knee jerks were normal and her hemoglobin 70 per cent

The carotid sinus reflex was negative In

view of this fact and the presence of a diastolic aortic murmur the thought of lues had to be considered The blood sedimentation reaction, however, on two occasions (one year apart) showed fairly normal figures, the first test gave an average of 8 mm, the second 15 mm per hour To exclude lues more thoroughly, Wassermann tests (including the Kolmer) were done The results were negative

A diastolic aortic murmur in a person with a wide expansile aorta, without a history of rheumatic infection, would be taken to indicate lues, despite the negative Wassermann The normal sedimentation rate, however, excluded active syphilitic disease Diagnosis Chronic rheumatic aortic insufficiency complicated by hypertension and paroxysmal tachycardia

To further illustrate how the knowledge of this symptom triad may be applied to clarify other apparent imponderables, a case of combined syphilitic and sclerotic aortic disease will be presented This diagnosis would be difficult with the usual clinical methods The necessity for such an attempt arises particularly in the indication for treatment, since active specific therapy applied to an uncomplicated case of atherosclerosis might react disastrously

M B, a 50 year old obese woman weighing 232 lbs, and only 5 ft in height, developed dyspnea and precordial pain on exertion 3 years ago One year later attacks of cardiac asthma followed by precordial pain during the night, came on In one of these paroxysms she felt as though she were dying The attacks would awaken her from sleep and compel her to sit in a chair with her legs hanging down in order to ease the breathing Urination occurred 2 to 3 times a night but was reduced during her asthmatic attacks The patient felt warm even in cold weather

A significant point in her family history is that out of 10 children only 3 are living, the rest died in infancy She had no spontaneous miscarriages however

Examination Pulse 96, respiration 46, deep, labored and noisy, B P 220/130, and the aorta was wide on fluoroscopy and percussion. On x-ray the lungs looked congested and hazy. The breathing was costal and the diaphragm was almost immobile during the attacks. She had a number of these in my office. During one of them, her breathing rose to 120, she was pale, perspired profusely and could not lie down. Heart sounds were loud, regular, with no murmurs, the rhythm at the apex was pendular. Lungs. A few submucous râles were heard over the lung roots, but not at the bases.

The urine contained albumin, and gave a 3 plus urobilinogen reaction, sugar was negative and specific gravity 1018. The Wassermann on the spinal fluid was 4 plus. The average blood sedimentation rate was 24 mm per hour.

The Hering reflex was positive on the right side.

CAROTID SINUS REFLEX

Pulse Beats per 10 second Period

	Right side	Left side
Before test	15	15
During test	8	15
After test	15	15

Diagnosis Tertiary lues is undoubtedly present. The high infant mortality and the positive spinal fluid Wassermann bear this out. We cannot, however, explain the positive Hering reflex and the hypertension without the diagnosis of arteriosclerosis. This reflex, even by itself, suggests aortic or coronary sclerosis. Attacks of cardiac asthma in my experience are more commonly present in non-luetic than in specific vascular disease. Therefore the diagnosis of combined syphilitic and atherosclerotic aortic disease was made.

A practical clinical point in this case was the "feeling of warmth in the skin" that this patient experienced. The close connection between the calibre of the arteries and the warmth (rather than the color) of the skin, has been emphasized by the recent studies of Sir Thomas Lewis¹⁰. The

relation between peripheral vascular dilatation and cardiac asthma has been shown by Eppinger, Papp and Schwartz¹¹. According to them it is the removal of the normal resistance in the arterioles that permits the blood to surge through the periphery and overwhelm the heart and lungs. These organs drown, so to speak, in the huge stream of blood coming from the periphery during an attack of cardiac asthma. Based on this principle, I have constructed an apparatus called the "Venostat" in order to shunt the blood in the four extremities, and so reduce the engorgement of the heart and lungs. The instrument consists of four blood pressure cuffs in series with a manometer. These are inflated to diastolic pressure and kept at this level for 10 to 15 minutes and gradually deflated. During the compression of the extremities, the blood pools in them because only the veins, not the arteries, are obliterated by the pressure of this degree. This whole subject has been fully dealt with in my paper on dyspnea¹².

Venostasis was applied to this patient and the asthmatic attack stopped in about 5 minutes. This was repeated whenever the attacks recurred. It was not very long before we could keep the patient comfortable with only one application a week.

SUMMARY

The diagnostic triad of syphilitic aortitis consists of angina pectoris, a negative carotid sinus (vagus) reflex, and a rapid blood sedimentation reaction.

The variations and pitfalls of each of the symptoms are individually discussed.

Agranulocytosis: Its Classification*†

Cases and Comments Illustrating the Granulopenic Trend from 8,000 Blood Counts in the South

By STEWART R. ROBERTS, M D , F A C.P., and ROY R. KRACKE, M D ,
Atlanta, Georgia

THIS new disease that we call agranulocytosis is an important addition to the list of dangerous diseases. A biologic condition exists in which the granulocytes are removed from the bone marrow and the blood stream. This is apparently a relatively new condition which emphasizes the necessity for blood examinations, and the fact that the granulocyte is apparently a biologic necessity for life, opens up a whole new world for research upon the blood. In no other condition is there so clearly an opportunity to study possible functions of these cells that have hitherto been unknown. A brief illustration is of value. For four days a strong man fifty-eight years of age feels sluggish and tired, the fifth day has a chill and fever, the sixth day, a higher fever; the seventh day, a slight redness of the throat and a restless stupor, the eighth day, coma and death. There is a negative history of infection, a negative blood culture, only an absence of granulocytes in the blood stream and in the marrow an absence

of granulocytes, myelocytes, and myeloblasts. What is it, and why is it?

Evidence has been presented in a previous paper¹ which showed the cycle of events in this disease. These events develop and follow in an orderly sequence. We have had nothing like it before either in biology or in medicine. In the beginning there is as yet no demonstrable infection, but only a selective hypoplasia or aplasia of the myelocytic cells of the bone marrow. The myelocytic series of cells either completely or nearly completely disappears. About four days after this event, the granulocytes are either absent or nearly absent from the blood stream. About two days after they disappear from the blood stream, the clinical onset begins, often in severe cases with dramatic suddenness, with collapse, chill, fever, red throat or ulceration of the mucosa, and stupor and death unless the granulocytes quickly reappear in the blood stream, because the marrow has begun to make myelocytes. If, and when, sepsis develops, it is a result and complication of the disease rather than a cause.

When the clinician first sees a case sick enough to send for a physician, the patient has usually already gone

*From the Emory University Hospital, Atlanta, Georgia.

†Read at the Baltimore Meeting of the American College of Physicians, March 27, 1931.

through the first three stages of the disease, and death or sepsis or both are at hand. The three stages in order are bone marrow onset, blood stream onset, and clinical onset. The sepsis follows the disappearance of granulocytes from the marrow and blood. And then absence, after two to four days, more or less, causes characteristic mental and physical collapse and a decreased resistance to bacterial flora. Hence the complicating sepsis may result from the variety of bacteria ever present upon the alimentary mucosa and normally prevented from entrance and activity because of the quality of resistance conferred perpetually upon the tissues by the granulocytes. The complete absence of the granulocytes for a period of seven days, more or less, is probably incompatible with life. Immunity in the fullness of its powers is dependent, in large part at least, upon the persistent, daily contributions of these cells. The restoration of myelocytic activity in the bone marrow is apparently the only hope of recovery. Hence those cases that live long enough to develop sepsis have a better chance of recovery. Sepsis, or sterile abscesses, may be therapeutically valuable. Dysfunction of the myelocytic series may recur again and again, causing recurrent attacks of the disease.

As one studies the disease and its intimate problems, its very largeness appears and distinctions begin slowly to separate themselves one from another. The idea of a group of diseases and conditions whose very essence is a decrease in the granulocytes begins to assert itself. This decrease varies from a transient disease, a mild acute

granulopenia to complete disappearance of granulocytes and a tragic blood disease called, among other names, agranulocytosis. It carries with it so far as is known a definite pathology, and certainly a definite series of onsets, that entitles it to be regarded as a disease entity until proof is afforded that it is the result of, or a symptom of, some disease or condition. One studies the books on diseases of the blood and finds in the indices long columns on leucocytosis and but a few scant references to leucopenia, and those chiefly copied from other books and papers. Far more space is devoted to leucocytosis than to leucopenia or to the functions of the leucocytes or to both combined. What indeed is the meaning and what are the ramifications of leucopenia? For example, there are the cases of granulopenia even to the complete absence of granulocytes which result from poisons, septicemias, irradiation, and which characterize some primary and secondary anemias and leukemias and certain acute infectious diseases. And then as one studies several thousand blood counts made under identical conditions of climate, altitude, locality, and identity of race and technique, the impression forcibly asserts itself that the granulocytes collectively are not only mobile, but exceedingly labile as well, far more so than any other blood cell. They enter the blood stream in showers and die in showers, their ups and downs are frequent, the count is up now, the count is down now, but out of all these variations more facts and new groups emerge, revolving around the central fact of a granulopenia. In a large series of blood counts a considerable

minority present a granulopenia, relatively acute in one patient, relatively chronic in another. It is to this phase of granulopenia that we desire to contribute a few facts, tables and conclusions, after a brief consideration of a classification that for the present seems practical.

One very important point to be borne in mind is that the life of the granulocytes in the blood stream is approximately four days, or seventy-two hours, a fact gained by animal experimentation.² The normocyte lives about thirty days. The leucocyte must function very intensely to have so brief an existence and its functions likewise are probably most complex. The functions of the granulocytes are probably more complex and important than hitherto believed. Their important rôle in the ingestion of dead and living bacteria, and their service as a source of important proteolytic ferments has long been recognized. Much evidence has accumulated to indicate that these cells may be the chief source of supply for many of the various types of immune bodies, such as hemolysins, bacteriolysins, precipitins, etc.³ Therefore, when the granulocytes are markedly decreased or when they disappear, the resistance of the patient may fall to a low ebb and easy bacterial invasion may result.

There is evidence that a granulopenia is a more important biologic state and blood condition than it has been considered. An attempt to separate the granulopenias one from another and to classify them may be rather early, in that the classification may have to be revised again and again with new knowledge. Nevertheless it af-

fords us a mental picture of the divisions that make up the group and that constitute the basis for future study.

THE GRANULOPENIAS

1. Acute granulopenia of unknown cause
2. Chronic granulopenia of unknown cause
3. Acute agranulosis with or without resulting sepsis
4. Acute recurring agranulosis with or without resulting sepsis.
5. Chemical granulopenia, due to chemical poisons as benzol and arsenic
6. Septic granulopenia, the result of general or localized septic processes
7. Irradiation granulopenia, the result of exposure to roentgen and radium rays
8. Anemic granulopenia, the condition accompanying certain splenic, aplastic and pernicious anemias, acute aleukemic lymphatic leukemia, lymphatic leukemia and certain secondary anemias with bizarre proportions of the lymphocytes and monocytes
9. Infectious granulopenia, the condition accompanying certain acute diseases as typhoid, typhus, measles, mumps, malaria, influenza, dengue fever and certain pneumonias
10. The granulopenia of Roseola infantum, also called Exanthem subitum

We wish to discuss the first two divisions with cases and comments upon them, after a brief discussion of agranulosis, items 3 and 4.

Acute Agranulosis, With or Without Resulting Sepsis

This is the more common type of the disease. In the cases that die before the onset of sepsis the overwhelming collapse from the mere and continued absence of the granulocytes is so great that death occurs before ulceration, necrosis or septicemia have had time to develop. Only a mild redness of the throat may be present, utterly unable of itself to cause or hasten death. The case given on the first page of this paper illustrates death without sepsis. We consider a case that shows no evidence of sepsis and in whom blood cultures are negative to be non-septic unless at autopsy evidence of sepsis is afforded. One's own experience and the literature more generously, perhaps, afford examples of both varieties. Sepsis is to be regarded as a complication of agranulosis, a result of the loss of the protective immunity afforded by the granulocytes. It will be noted that we propose and have submitted the term "agranulosis" instead of "agranulocytosis." We believe this an improvement in the terminology of this disease, since it indicates the pathological process as clearly and possesses the added virtues of brevity, simplicity, and easy pronunciability.

ACUTE RECURRING AGRANULOSIS WITH OR WITHOUT RESULTING SEPSIS

The remarks just made apply equally well to these cases. There is only one difference, these cases always recover from one or more attacks and have a second or additional attacks. One thinks of the relapse and the remission in pernicious anemia. Every patient with the disease is to be re-

garded as a candidate for a second attack. If he recovers from the first attack, daily blood counts offer the only opportunity so far known to follow the granulocytes upward as they approach normal and downward if the second attack follows and develops. Such counts, if possible, should be made at the same time daily and by the same technician using the same pipette. The granulocytes will show a definite drop to a few granulocytes or to complete absence about four days before the clinical onset begins. This is a better time to begin treatment than after waiting for complete agranulosis. One of our reported cases illustrates the recurring type. The literature affords examples of many recurrences in the same case and at varying intervals. Mild cases may recur at shorter intervals. The second and fatal attack in a man of sixty came ninety days after the first attack. The cause of the recurrence is an interesting problem. In the attack of pernicious anemia, the granulocytes often decrease with the normocytes and the characteristic granulocytes of pernicious anemia seem to be the first blood evidence of the attack and the last after remission has begun. If one could explain agranulosis, he might also be able to explain pernicious anemia.

ACUTE GRANULOPENIA OF UNKNOWN CAUSE

Here we are entering upon a rather chartless sea and much unexplored territory. Three illustrative cases may picture the types.

(a) A man of fifty-one in good health had been under much nervous and mental

strain for two years. At intervals during 1930, he noticed periods of a few days introduced by sleepy feelings, difficulty of waking, slowness and sluggishness of mind and body. After two or three days or a week, he would quickly become well again. A few small lesions of ulcerative stomatitis would occur at this period. On December 1, 1930, an attack came, worse than before, accompanied by heavy lids, sleepy feelings, weakness, a desire to sit and be still or lie and sleep. This attack lasted six days and the white cell count was as follows:

	White Blood Cells	Percent of Granu- locytes	Number of Granu- locytes
December 1	5200	55	2860
2	4500	51	2295
3	4200	48 (ulcers	2016
4	3600	40 of	1440
5	5200	50 mouth)	2600
6	6000	56	3360

For the first five days the patient felt very weak, especially so on the fourth day. He began to feel better on the fifth day though the ulcers were then just beginning to heal. Another attack came on Saturday, March 14, 1931. After a hard week with much loss of sleep and strain, he awoke with heavy, sluggish feelings, burning upper lids, heavy limbs, and through the day, objects were rather dim and distant, memory poor even for events three hours before, and all day a sleepiness. A blood count showed a Hb of 99 percent, W B C 6600 and a differential of N, 46, L, 53, M, 1. The granulocytes numbered 3036, and on the next day, 3428. There were no ulcers with this attack. This patient can now because of his feelings come for a count and describe the onset, and as he says, "feel his leucopenia."

(b) In infants with very red and swollen gums and negative physical examination otherwise, save for temperature of 105°, an acute leucopenia may be the only positive finding.

(c) We have a definite account of a physician who in April, 1927, had an attack of agranulosis with chill, fever, red throat, granulocytes absent, lymphocytes 80. A

second attack came thirty days later. "In the year and a half that followed, whenever I was not feeling well the white count always showed between 4000 and 5000 whites with a corresponding fall in polys. I could always tell when a leucopenia was present. Since my retirement in 1929, I have slowly improved in general health, but it has left me with a myocarditis, and a loss of thirty pounds in weight that I have never recovered."

We have here three varieties of cases. The first in the man is acute granulopenia. In the third case there were apparently similar attacks of acute granulopenia, but he had recovered from two severe attacks of agranulosis. Is acute granulopenia a first step toward agranulosis, a mere difference in degree only, or is it a separate condition? The curious observation of Dr. Hines Roberts⁵ on teething with inflamed and swollen gums, as correlated with the adult with his aphthous ulcers is interesting if not significant.

We have so long looked upon blood counts as the result of extra-hemic states and disease except in the case of primary anemias, and then we have tried hard to find such extra-hemic states, that it is rather difficult to turn the tables and try to find which is cause and which is effect, whether a fall in the granulocytes may be the cause of the subjective body feelings, the weakness and the sluggish inertia of mind and body in these cases. To explain the cause of the fall in the granulocytes is quite another matter. A falling granulocyte count causes symptoms, the greater the fall, other considerations being for the time omitted, the greater the evidence of collapse, provided the element of duration be

also taken into account. The strange disease of infants and children, first described by Zahorsky^a and called *Roseola infantum* and *Exanthem subitum*, pokes its problematic nose into the picture. Here is a disease without symptoms save fever and without signs save an extreme leucopenia of 3000 to 7000, 10 to 25 per cent granulocytes, 75 to 90 per cent lymphocytes, a lymphocytosis, a rash on the fourth day, (a leucocyte lives four days) a fast fading rash on the same day and a quick recovery.

A child of eighteen months was taken suddenly ill with high fever on May 3, 1930. There was a slight gastro-intestinal disturbance. Family history and past history of no importance. Examination negative except a temperature of 104°. The W B C were 3,000, N, 13, L, 86, M, 1. On the fourth day there was the typical rash of *Roseola infantum*. Temperature dropped to normal. Prompt recovery.

And then how much of the weakness in the acute infectious diseases is due to the disease itself and how much to the extreme granulopenia that accompanies it? Under this question might well be included certain cases of dengue fever, influenza without complications and typhoid without complications. Does this extreme leucocytosis in meningitis account for the amazing physical strength and endurance of certain cases as compared with the languor of certain mild influenza or dengue cases? And why is there a leucocytosis in pregnancy with so often the new health, the high spirits and the optimism of the pregnant woman? No matter what causes the leucocyte increase, do more granulocytes, a myeloid rise stimulate strength and energy?

CHRONIC GRANULOPENIA OF UNKNOWN CAUSE

We wish to discuss more fully, item 2 of the classification, namely, a condition which we call Chronic Granulopenia. In 1910, Cabot⁷ called attention to the association of "some forms of debility" with an increased percentage of lymphocytes, "due in fact to the absolute diminution of the neutrophils." Piney,⁸ in 1927, under the title "Leucocytic Pictures" interpreted a difficult case of a mentally defective man with a pain in the right iliac region who at operation showed adhesions around the cecum. The count showed 7,500 leucocytes of which the granulocytes were 48, the lymphocytes 49, and the monocytes 2 per cent. Cabot spoke of the condition as a "false appearance of lymphocytosis." References to similar counts occur in certain cases of the endocrine glands, and Clough⁹ refers to "debility" as one of the causes of the leucopenia. The intimation is rather common that this strange sameness of per cent and number of granulocytes and lymphocytes is the result of the debility, the adhesions, and the endocrine diseases. The lymphocytes are normal in number and size. In such counts the granulocytes and lymphocytes are about the same in per cent and number, so much so that we have referred to such an equality as the "fifty-fifty count," or, if persistent, a chronic granulopenia. If such a count is the result of debility, a neurosis, or, a chronic exhaustion, it is relatively unimportant, but on the contrary, if it may be the cause of such conditions, it becomes of real importance because it intimates that the origin of the syndrome may be in the

bone marrow and the weakness and debility be but a first degree of the real collapse that occurs in agranulosis when all the granulocytes are gone. We have reported a case in a woman who, in 1923, had a count of leucocytes, 7,400, granulocytes, 47, lymphocytes, 52, and monocytes, 1 per cent, or 3478 granulocytes to 3848 lymphocytes. Six years later this woman developed fulminating attacks of agranulosis and died in the second attack. In another case that developed, and died of, agranulosis, the count made was normal two years previously. But it is with these chronic granulopenias that we are primarily concerned and not with their relation to agranulosis. Wellman¹⁰ has recently reported an instance in which the patient complained of marked exhaustion with negative physical findings, but whose blood count was persistently low with a high percentage of lymphocytes. The relation of a few case reports will accent the type and the problems.

Case 1 N B A woman of sixty-one, well nourished, who complained of debility and gastric distress. Her chief complaint was weakness and lack of endurance. There was much mucus in the stomach and in the large bowel. Other examinations proved negative. She was a typical debilitated neurotic, always trying to be better. Her average count was 5,000, G, 50, L, 48, M, 2. In one differential count there were 17 "mudge" forms found, 100 cells counted. A sternal puncture showed myeloblasts, and myelocytes as well as young forms of granulocytes in degeneration with vacuoles, pyknotic nuclei, and a few cells beginning to disintegrate.

The contrast between Figure 1, from a case of chronic granulopenia, and Figure 2, from a case of acute agranulosis, is interesting.

Case 2 A M P A man of thirty-nine was first seen in June, 1922, height, six feet, three inches, weight, 140 to 150 pounds. Complaint was exhaustion and lack of endurance. Test meal, total acidity, 50, free HCl 32. Four counts were made from 1922 to 1931, as follows:

	Hb	R B C	W B C	G	L	M
1922	84	4,720,000	5,600	47	53	
1929	73	3,430,000	7,650	51	49	
1930	83	3,200,000	4,800	44	56	
1931	87	4,220,000	5,500	66	32	2

In this case the average of four counts over four years is 5,390 leucocytes, an average granulocyte count of 51 per cent, or an actual number of 2,749 granulocytes. An interesting finding in these patients is the occasional sharp variation in the percentage of granulocytes upward with the corresponding fall of the lymphocytes, and this whether the counts are made daily or from year to year. This is illustrated in the jump of the leucocytes in 1929 which, however, cannot be considered abnormal, and the rise in the granulocytes in 1931. The patient was of the opinion this last year that he was in better health than the years previously, business being so poor that he had been resting much more than usual.

Case 3 W A S A man of forty-eight, minister, weight 141 pounds, height 5 feet, 11 inches, same type physically, though not so tall. Complaint of exhaustion and gastric disturbance. Hypotension. Normal gastric acidity. This man was a research scholar of high intelligence. He "gave out so quickly," he said.

	Hb	W B C	G	L	M
1923	94	5,350	53	43	
1925	78	5,400	65	30	5

In two counts, two years apart, the leucocytes averaged 5,375 with 59 per cent granulocytes or 3,171.

Case 4 C A S A woman of forty-four complained of nervousness, indigestion and easy exhaustion. Weight 110 pounds, height 5 feet, 1 inch. Gastric acidity normal. Both ovaries were removed at twenty-seven. Examination negative. Hb 88, R B C, 5,400,000; W B C 1100; G 48, L 52, M 5. Granulocyte numbered 1,068.

FIG 1 Smear of bone marrow obtained by sternal puncture from a patient with chronic granulopenia. Note the evidence of cell degeneration, including irregularity of contour, vacuolization, loss of staining quality, and smudge-like appearance.

FIG 2 Smear of bone marrow obtained 24 hours before death from patient with acute agranulosis without sepsis. Note the absence of granular cells, and evidences of degeneration in those present.

The obtaining of bone marrow by puncture of the sternum has been resorted to in a few cases of agranulosis,¹¹ and there is unanimity of opinion that the essential pathology is a marked and practically complete hypoplasia of the myelocytic tissues. Sternal punctures twenty-four hours before death in one of our patients showed a bone marrow that was entirely devoid of granular cells of any type, including even the myeloblasts.

Such a picture may be contrasted with that seen in bone marrow obtained by sternal puncture from a case of chronic granulopenia. The essential pathology in this condition seems to be unusually severe, rapid degeneration of the granular cells before they have had opportunity to escape into the peripheral circulation. Bone marrow smears in Case 1, (last series, above), show large numbers of so called smudge cells or degenerate leucocytes with numerous poorly staining, irregular, vacuolated, but immature granular cells. Apparently there is either a poor quality of cell produced or an unknown influence is injuring these cells before they leave the bone marrow and before they attain maturity. Special fat stains on these preparations do not show that this is a fatty degeneration.

In an effort to determine whether or not any relationship exists between the degree of granulopenia and certain signs and symptoms, from a large series of patients seen in private practice, a statistical study of 8,000 records was made. The patients comprising this group, for the most part, were those seen in office practice and consultation in the diagnostic clinic of

one of us over the ten year period from 1920 to 1930. Therefore, the class of patients in this group lends itself admirably for such a study, since very few showed acute illnesses in which the hematological findings would be temporarily abnormal. They were ambulatory patients and were not convalescent from any acute infectious disease. The study was conducted with the chief view of ascertaining the number showing varying degrees of granulopenia, comparing the signs, symptoms, and diagnoses of this group with those of the control group, and determining the influence of age and sex in the granulopenic group. The study is presented here in the form of tables and charts, and in certain deductions from the compiled figures, which may be made.

In order to properly classify the 8,000 cases into either the normal or the granulopenic group, an arbitrary standard of normality for the granulocytes was established. Accepting the figure of 6,000 leucocytes per cubic millimeter with 67 per cent neutrophils as being a low standard for normal,^{12 13} all counts below that figure were regarded as showing evidence of granulopenia. Converting this figure into terms of absolute numbers of granulocytes, any count showing less than 4,000 granulocytes per cmm was regarded as being granulopenic. In accordance with figures for normal leucocytes as expressed in various standard text books and by several authorities, we believe that 4,000 granulocytes per cmm represents a low, conservative estimate for normality.

It should also be considered that these white cell counts in this group were usually carried out on ambula-

toiy patients, in whom the total cell count is probably higher than it would be at bed rest under basal conditions. The importance of this phase of blood counting has been well stressed by Garrey.¹¹ The time the counts were made in this series was usually in the mid-forenoon or mid-afternoon and at a time when the patient was oftentimes on his first visit to the clinic and always at a time when he was undergoing a variable amount of strain and emotional stress coincident with the procedures carried out in a diagnostic examination. From a consideration of the above factors, it is probable that the white cell counts in this series were actually lower under normal conditions than indicated by these records.

From a study of the tables, it will be noted that one out of four patients showed a granulopenia. In the granulopenic group the count ranged from 4,000 down to below 1,000, with a gradual decrease in the number of patients in the more severe degrees of granulopenia.

Total number of records examined	8,000
Number of granulopenias	1,881
Number of normal counts	6,119

COMPARISON OF ACES WITH DEGREE OF GRANULOPENIA

Neutrophile Count	Males	Average Age	Females	Average Age
0-1000	5	47	3	44
1000-1500	13	27	15	39
1500-2000	30	39	59	41
2000-2500	102	40	103	37
2500-3000	126	39	160	41
3000-3500	300	40	335	40
3500-4000	227	45	403	38
Normal Count	2016	39	3274	33

Average of 1000 counts in 1919-20	9022
Average of 1000 counts in 1930-31	8926

GRANULOPENIC GROUP

Counts from 1-1000	8
Counts from 1000-1500	28
Counts from 1500-2000	889
Counts from 2000-2500	205
Counts from 2500-3000	386
Counts from 3000-3500	635
Counts from 3500-4000	630

Since acute agranulosis may be seen chiefly in the patient with granulopenia, this finding seems to be especially significant. In the granulopenic group, ten per cent of the patients came to the clinic with the chief complaint of weakness, in the control group, only five per cent gave this as a chief complaint. This finding seems important since much evidence has accumulated to indicate that weakness, exhaustion, fatigue, and tendency to sleep may be the chief results of a depressed granulocyte count. In the granulopenic group, eighteen per cent gave a chief complaint of nervousness, obscure as the term is, while twelve per cent registered this complaint in the control group.

GRANULOPENIC GROUP

Patients with chief complaint of weakness	190
Patients with chief complaint of exhaustion	75
Patients with chief complaint of nervousness	325
Patients with diagnosis of psychoneurosis	398

NORMAL GROUP

Patients with chief complaint of weakness	330
Patients with chief complaint of exhaustion	246
Patients with chief complaint of nervousness	732
Patients with diagnosis of psychoneurosis	1254

In the granulopenic group, twenty-three per cent of the patients were be-

tween the ages of forty and fifty, in the control group twenty-seven per cent were between thirty and forty. In the granulopenic group, fifty-six per cent were females. Therefore, the type of patients seen most frequently in the granulopenic group, was women between the ages of forty and sixty.

GRANULOPENIC GROUP

Patients in the first decade	46
Patients in the second decade	138
Patients in the third decade	307
Patients in the fourth decade	417
Patients in the fifth decade	434
Patients in the sixth decade	344
Patients in the seventh decade	195
Males	803
Females	1078

NORMAL CONTROL GROUP

Patients in first decade	168
Patients in second decade	440
Patients in third decade	1216
Patients in fourth decade	1661
Patients in fifth decade	1046
Patients in sixth decade	946
Patients in seventh decade	642
Males	2916
Females	3203

COMPARATIVE STUDY OF LEUCOPENIC GROUP AND CONTROL GROUP
AGE

	Leucopenic Group (1881)	Control Group (6119)
Patients in first decade	2.4%	2.2%
Patients in second decade	7.2%	6.0%
Patients in third decade	16.3%	19.4%
Patients in fourth decade	22.0%	26.8%
Patients in fifth decade	22.8%	17.4%
Patients in sixth decade	18.2%	15.4%
Patients in seventh decade	10.3%	10.2%
Males	41%	48%
Females	56%	52%
Average age males	41.1%	39%
Average age females	39.3%	33%

CHIEF COMPLAINT

	Leucopenic Group (1881)	Control Group (6119)
Chief complaint of weakness	10.1%	5.4%
Chief complaint of exhaustion	3.9%	4.0%
Chief complaint of nervousness	17.3%	12.0%
Diagnosis of psychoneurosis	21.1%	20.6%

In an effort to determine whether or not any general differences may be manifest in blood counts done ten years ago and today, an average of 1,000 consecutive counts made in 1920 was found to be 9022, while the average of 1,000 counts made in 1930-31 was 8926. Leucocyte counts, as a whole, therefore, seem to be about the same as ten years ago. Since acute agranulosis has apparently been recognized within that period, this finding may be of some importance.

SUMMARY AND CONCLUSIONS

1. The importance of the leucopenias is emphasized.
2. The biologic and diagnostic importance of a leucopenia is probably as great as of leucocytosis.
3. A classification of the granulopenias is submitted.
4. Two conditions, acute and chronic granulopenia, are described.
5. Agranulosis is classified in the general group of the agranulopenias.
6. The relation of acute and chronic granulopenia to agranulosis is discussed.
7. The problem of granulopenia is studied in 8,000 private clinic patients.
8. One out of every four patients may be expected to have a mild granulopenia.

9 One out of two female patients between the ages of forty and sixty may be expected to show a mild granulopenia

10 The complaints of weakness, exhaustion, or fatigue are twice as frequent in the granulopenic patients as in those with normal white cell counts

11 White cell counts done today show no difference from those done ten years ago

12 A clinical syndrome, consisting mainly of weakness, easy exhaustion, tendency to fatigue, loss of strength and inertia, associated with a diminished number of granulocytes, is described

13 The severity of the symptoms is largely dependent upon the degree of diminution of the granulocytes, with complete collapse in the most severe type, namely, agranulosis

An Evaluation of the Skin Test in Allergy*†

By H. L. ALEXANDER, M.D., *St. Louis, Mo*

THE word "allergy" as used in these remarks, has to do solely with the clinical condition that is represented by the asthma-hay fever-eczema group of cases. The conception of this type of allergy, as well as its rapid and extensive development during the past fifteen years, has been dependent largely on the skin test. The test consists of the introduction of extracts of foreign substances called "allergens" or "atopens," into the dermal cells. If there be antibodies present to the particular allergen applied to these cells, a reaction in the form of a wheal with a surrounding erythematous zone will appear.

When the test was first developed, it was assumed that an individual whose test was positive to a given allergen was constitutionally sensitive to this foreign substance. By the same process of reasoning, it was inferred that if the nose or bronchi were sensitive, the skin should be sensitive also. This point of view, which is still held by many, has not only been challenged, but from the clinical standpoint, at least has been shown to be fallacious.

*From the Department of Medicine, Washington University, and Barnes Hospital, St. Louis.

†Delivered at the Baltimore Meeting of the American College of Physicians, March 24, 1931.

Allergy is a localized process, and only certain organs of the body manifest it. This holds true, not only for man, but it is seen during anaphylactic shock in animals. The tissues participating in the process have been spoken of as "shock tissues." In humans, most allergic manifestations occur in the skin, in the respiratory tract and in the gastrointestinal tract. Allergy of the heart, thyroid, pancreas, bone, etc. are unknown. Not only do the skin, the respiratory and gastrointestinal tracts bear the brunt of most of the clinical expressions of allergy, but the rule is that but one, or a portion of one, of these systems is involved during a given attack. A patient usually has hay fever, or asthma, or urticaria, or intestinal spasm, and less frequently has two or more of these. In other words, his bronchi alone, for instance, may be clinically sensitive. This is demonstrated by the simple example of the child who has asthma whenever it eats wheat. Wheat, or its digestive derivative, is absorbed into the blood stream and circulates throughout the body. Only asthma results, because in the bronchi alone does the allergen find antibodies with which it will react. The skin may be sensitive, or it may not. If it is, a skin test to wheat should be positive; if not, no positive skin reaction is possible.

With this conception of allergy stated, one may inquire as to the value of the skin test. A difficulty at once arises, because none of the elements that comprise the test have been standardized. There is no one accepted method for preparing allergens, either in their dry state or as extracts. The introduction of allergens into the skin may be done in one of two ways, namely, the scratch method or the intradermal method. The latter is the more sensitive. There is no prescribed amount or strength of allergen introduced into the skin. And finally, the reading of the reactions is entirely an individual matter. This is, perhaps, the most important element, because if the skin be sensitive to a given allergen, some degree of reaction will usually come with any method. On the other hand, a delicate skin, or trauma, will often obscure results. The fact remains, that two observers who use essentially the same technique may report a very great discrepancy in results. One example records the divergence of 25 per cent and 74.9 per cent of positive reactions in bronchial asthma with the same method.

It has been stated that inasmuch as allergy is a localized process, the skin is not always sensitive. There are certain probabilities based on statistics which are familiar to those who deal with allergy. For instance, positive reactions occur more frequently in younger individuals than in adults and tend to disappear toward old age. Positive reactions to foods occur most frequently during the early years of life etc. The reliability of the test however, can be stated only for a given technique performed repeatedly by the

same individual. To arrive at statistics otherwise, requires a consideration of the general results obtained by many observers, each using his particular method. The present study is based on such figures.

TABLE I—POSITIVE SKIN REACTIONS IN 11,443 CASES OF ALLERGY

Allergic Manifestation	No Observers	No Cases	No Positive Reactions	% Positive Reactions
Hay Fever	9	4381	4076	93.2
Vasomotor Rhinitis	8	1020	568	55.7
Eczema (infant and adult)	10	775	408	52.7
Bronchial Asthma	13	4809	2536	52.7
Gastro-Intestinal A1	4	460	122	26.5

These figures coincide with the experience of many who treat large numbers of allergic individuals. There is a prevailing impression that for a reason as yet unexplained, the test is very reliable in hay fever. Here the skin and nasal mucosa appear almost always to be sensitive together. That this has little to do with tissue structure or function is demonstrated by the fact that in allergic rhinitis or "perennial hay fever," wherein the process in the nose is identical with that of annual hay fever, positive skin reactions occur in but 56 per cent of the cases. No sufficient data concerning positive reactions in urticaria and angioneurotic edema could be found but the skin test in these conditions is notoriously unreliable.

Given, then, the average incidence of positive skin reactions in various

manifestations of allergy, the question arises as to whether there are any circumstances which may modify the interpretation of positive reactions. Unfortunately, there are. In the first place these reactions are not always constant. Positive reactions are arbitrarily indicated by + signs. A 1+ indicates a faint response and a 3+ or 4+ a large wheal. With the exception of response to pollens, positive reactions frequently vary in their intensity from time to time. A 2+ reaction may disappear a month later and reappear as 1+, or a negative response in a given case may not remain so, whether or not specific treatment had been given. For that reason, retesting as a routine, is practiced by many. Time will not permit a discussion of the possible factors underlying this phenomenon. Not only may there be variations in positive reactions at different times, but it has been shown that in a given case there may be a wide variation of response if the test is applied simultaneously to various sites of the skin. When these sites are sufficiently varied, a negative reaction may be recorded for the test done on the leg and a 3+ for the one applied to the back (Figure 1). In such instances, it becomes difficult to estimate the degree of an individual's sensitivity by the skin test. The only thing one is permitted to say in that case, is that a certain portion of the skin of the back is sensitive, whereas that of the leg is not.

There is still another consideration of a positive skin reaction which leads to trouble, namely, the appearance of such a response to an allergen which obviously has nothing to do with the

Fig. I

0.02 cc. of a 1-10,000 dilution of ragweed pollen extract injected into various sites of the skin of a hay fever patient

Figures—Area of wheals measured in square centimeters 15 minutes after injection

history of a given case. Such a reaction is termed a "false positive." These occur so frequently that each positive reaction to be considered relevant should be tested clinically. This is done by the withdrawal of the given allergen from the patient's environment with subsequent subsidence of symptoms, and the re-introduction of the allergen with reappearance of symptoms. This, after all, is the only reliable check on positive reactions.

From these data, one may justifiably be discouraged with the skin test, when it is applied to most allergic conditions. This discouragement has been reflected in recent years by many who were led to believe in the adequacy of the test. They have been told that a negative response reflects on their performance of the test, whereas it is not a question of improper technique but of some condition inherent in the patient. (Some specialists use three hundred or more allergens routinely, but their results do not indicate that success lies in mere numbers.) These remarks are not in-

tended to convey the impression that the skin test should be discarded, for it is as yet, by and large, the best means at hand for determining specific sensitivity, and when it works successfully it is most satisfactory.

Allergy is still growing apace and the number of sensitive individuals is, according to statistics, astounding. This fact demands that the great majority of such cases should be treated by the internist rather than by the specialist. An appreciation of the subject is, at best, difficult, and the vast amount of literature concerning it makes things no less confusing. As long as the skin test offered a reliable means of determining the specific allergen responsible for symptoms, there was a fair chance for anyone to work out a case. Since the test appears unreliable and difficult to interpret, some other approach becomes necessary.

One fact which offers a general, workable basis is derived from statistics, namely, that by far the greatest number of patients with allergy, some 80 per cent or more, are sensitive to comparatively few allergens. These, excluding pollens, listed in order, are shown in tables IIA and IIB.

If reliable extracts of these 25 allergens together with a few pollens most common to a given locality be applied to all cases, the chances are that if reactions are to occur at all, they will appear with them. These are the allergens to which one is most exposed. This fact is evident from the high incidence of reactions to such substances as wheat, egg, milk, feathers (pillows), and orris root, (face and talcum powders). Likewise foods that are starred in Table IIB are those

TABLE IIA—INCIDENCE OF REACTIONS WITH COMMON ALLERGENS (32,182 TESTS)

Pepper	452	79	17.5
All others less than 5%			

*Figures taken mainly from cases of infantile eczema

which are given to infants who, when hypersensitive, are particularly susceptible to food allergens. In dealing with adults, one may omit these particular extracts and thereby lessen the number of allergens to be used routinely

Should no positive reactions be obtained, if the patient be placed in an environment wherein he will not come in contact with these comparatively few allergens, symptoms will disappear in most uncomplicated cases. This is the basic anti-allergic régime in one form or another, on which most specialists place their patients, because these are

the allergens to which sensitivity is most likely to exist. To determine the allergen at fault, the patient is exposed to one or more of the substances suspected until symptoms appear

A skin test correctly interpreted leads to a short cut, and it therefore should be done, at least with the allergens mentioned above. To be sure, there is a residuum of cases sensitive to other substances, or with complications, that require special treatment. A great many patients, however, may be treated successfully if they are protected from some of these common allergens.

The Influence of the Practitioner of Medicine in Guiding the Public Towards Health*

By HAVEN EMERSON, M D., *New York City*

THE terms of the title assigned to me are too ambiguous to pass without definition. By the practitioner of medicine we usually intend to include only those physicians and their professional associates who earn their living chiefly, if not entirely, by using the sciences and arts of medicine for the diagnosis and treatment of disease as it is expressed in individual patients. Such physicians are by implication distinguished from those who are concerned with the prevention of disease through the authority and resources of official and volunteer health agencies. As I understand the use of words, both groups of physicians and their professional associates, by whom I mean nurses, social workers, dentists, and sanitarians, are practitioners of medicine, the private practitioner, general or special, being concerned chiefly with cellular and personal pathology, the practitioner of public health with social and geographic pathology. Knowledge of prevalence and prevention among the public of such diseases as are believed to be preventable is gradually approaching an exactness comparable to that of the processes and

expression of disease in the individual.

The function of the practitioner of individual medicine is conceived by the laity to be almost wholly the discovery of the nature of, and relieving the symptoms due to disease and defects of all varieties, whether of body or mind; that is to name and to treat disease, to relieve symptoms if possible, to cure sometimes, often to postpone death, and usually to give such comfort and courage in the presence of disease that can with our present knowledge be *neither* cured nor relieved, as the quality of human character permits.

The function of the devotee of public health is, in the words of England's eminent health officer, Sir George Newman, "to make a better tabernacle for the soul of man to inhabit," or in less imaginative terms, to adjust mankind and his environment so successfully that each individual may attain the amplest satisfaction in life of which he is capable, within the limits imposed by his inheritance of qualities and the economic status which society allows him.

Obviously the basic sciences upon which these two closely inter-dependent fraternities of the medical guild have erected the structure and conduct of their work are identical, the techniques and methods of application however

*Delivered before the American College of Physicians, March 24, 1931, Baltimore, Maryland

differing widely As the specialist in personal medicine extends his skill and knowledge far beyond the subject matter of his undergraduate curriculum, he who would deal competently with the group, the communal, the social expression of disease, and seek to accomplish prevention in the mass or the demos must add some understanding of vital statistics, sanitary science, epidemiology and social organization.

When using the term public health we rarely express clearly what is in our minds We are apt to mean merely the sum of individual healths statistically expressed as morbidity or mortality, and their opposites vitality and longevity. To paraphrase an old medical aphorism "There is no health; there are only healthy people."

In no true sense is there such an entity as public health, for the public, the demos, the crowd, the community of whatever size is in a sense perpetual if not immortal and yet lacking personality, and without birth or death can in only a figurative sense be credited with so intimate a quality as health

It is the public as a composite of individuals of all ages and conditions which we wish to guide towards health

May I, in further interpretation of the title, be permitted to sketch briefly the two eras through which we have in a measure passed and suggest the significance of the one at the threshold of which we now stand expectant but confused

From just prior to 1850 until almost exactly 1900 public health established itself in general esteem by the application of sanitary science and the authority of sanitary law to the control of communicable diseases, chiefly those

conveyed by discharges of the intestinal tract, and those transmitted by vermin. The environment was the major issue and by improvement of water supplies and waste disposal, by housing reform and a generally higher level of municipal housekeeping the cities were brought to be a safer place for health than was rural America During this era of sanitation the health officer and his supporting board of health were almost alone in the community in their concern with the application of medical knowledge to the conduct of public affairs. Their functions were chiefly conceived and executed in the spirit of the police, and often mainly for disciplinary purposes Except during the throes of an epidemic, or threat of one they were unheard and unsung, and they lacked support of voice, opinion, or funds from the general public or volunteer associations.

With the initiation of the educational and social effort of the local committees for prevention of tuberculosis in 1900 and the following years, and the subsequent creation of the National Tuberculosis Association, there came a new, powerful and effective element which has stamped its character upon every phase of public health work here and abroad for the past thirty years We may speak of this second era as that of public instruction It was the statesmanship of Prudden, Janeway, and Biggs in New York and of their counterparts in other eastern seaboard cities which determined the features of this innovation in public approach to the then dominant cause of death. With the simple trio of facts in mind that tuberculosis is communicable, pre-

ventable, and curable it was clear that until every household in the land knew their significance, and could be persuaded into action, no amount of sanitary law or authority, no regulations or restrictions could be expected to avail.

It would be quite superfluous in addressing a medical audience today to elaborate upon the developments in the various special fields of health endeavor which have at times threatened to submerge science and reason in a welter of unrestrained propaganda and publicity. Enough to remind you of the essential similarity of plan by which social hygiene, child health, mental hygiene, heart disease, cancer, blindness, etc., have been brought to public notice in the successive waves of zealous health promotion.

It is true that state laws have in some places required the inclusion of simple facts about the causes and means of prevention of the common communicable diseases, Michigan leading far in the van. But it will be admitted I believe that it has been through the instrument of volunteer and chiefly lay organizations that the people, the public press, legislators and public officers have been reached with the message and promise of preventive medicine. If other evidence were lacking it would suffice to recall that the first division or bureau of a city health department entrusted with health education dates from 1914, and that the first such division of a state department of health was created in the following year.

You know, I am sure, the significant accomplishment of this second era, the stage of widespread public information about health and its attainment, dis-

ease and how to avoid it. Authority of statute law or local ordinance could not assume to require people to seek medical opinion for symptoms or signs of disease which in the private opinions of 1900 did not justify personal anxiety, prevent present enjoyment of life, seem to threaten self support or actually communicate disease to others. And yet prevention depended upon preparedness and priority. Every lesson of the laboratory and clinic taught us that a wide range of the less acute preventable diseases and postponable causes of death could be controlled or reduced only if the patient's discomfort was displaced by a physician's pre-science as indicator for precautionary treatment or adjustment in the way of life.

The clinic of special skill for early recognition of disease, for its consecutive and persistent treatment, including guidance socially, economically, educationally, and often vocationally, was the professional resource towards which public health information was designed to persuade people.

We are still accruing incalculable benefits from the era of sanitation. We have hardly abated a jot in our devotion to the methods and objectives of the era of public information.

And yet we are fairly launched upon a most promising third phase, the era of general personal participation in health, and it is to a further definition of this, and with the hope of convincing you of the desirable function of the general practitioner in advancing it now and in the immediate future, that I wish to devote the main argument.

The date of origin of this era can

be quite precisely given as the Spring of 1922 when both the National Health Council, and the American Medical Association declared themselves of the belief that further advance in the application of preventive medicine demanded the widespread practise of the periodic health examination as a part of the service of the family practitioner of medicine.

This was not even nine years ago a new idea, for experience with a wide variety of public clinics, created under health authorities, in schools of medicine, in hospitals, and under social and philanthropic agencies had brought to accounting and attention an undreamed of mass of submerged and neglected invalidism, in persons carrying on their work and avocations without thought of complaint or belief that there was any other lot for them than handicapped existence.

Out of every ten persons coming for expert opinion on a possible or suspected pulmonary tuberculosis, seven are found to be non-tuberculous, and yet bearing a burden often of another remediable or at some stage preventable condition. In every hundred children presenting themselves for schooling at least 65 per cent are found to have one or more potentially if not at the time, disabling and preventable defects. Every review of bodily fitness among men and women whether for industrial or military needs, or for civil employment, reveals the extent to which unnecessary and readily avoidable disease or disorder of function and structure can prevail without knocking at the attention of the patients or driving them to seek medical care.

What is proposed in order to put to

work the knowledge of prevalence and prevention of disease, which has been accumulated with care and precision in hundreds of educational and research institutions, and by the contributed devotion to fact of still more thousands of medical practitioners? What is the influence which physicians in their personal relationship hold which is of greater persuasiveness towards health than can ever be the authority of law, its enforcement by public officials or the ingenuity and plausibility of generalized popular health promotion through slogans, campaigns, drives and objectives of volunteer or non-official health agencies?

The influence, potential and actual, of the practitioner of medicine, though small in amount at present and applied but haltingly and with diffidence, in persuading the public towards health is seen at its best in pediatrics and obstetrics. It consists in his knowledge of healthy structure and function, deviations from which he has in the past been chiefly concerned with detecting, measuring, and treating. Physiology rather than pathology is the basis upon which his power of direction of human life in health is built.

The obstetrician whether in the person of the specialist or of the general practitioner has accepted evidence accumulated by studies of a statistical and epidemiological character to the effect that prenatal supervision of the expectant mother can be relied upon to reduce the proportion of stillbirths, lower the neo-natal mortality rate, i.e., deaths in the first month of life, and increase the probability of survival of the mother with a minimum of post partum morbidity. Incidentally good

prenatal care at present carried out contributes largely to a reduced prevalence of syphilis. In his capacity of private practitioner of medicine the physician called upon to guide the pregnant woman can and does contribute to the sum total of community health to a degree and in a quality of service which it is most unlikely any other professional agency can replace.

Health departments may for the *dependent* expectant mother facilitate by organization the provision of medical and nursing care during pregnancy, and at and after confinement, but it will always remain for the private practitioner to exert the greatest influence in this field.

At the present time probably not as many as one quarter of the expectant mothers of this country are receiving a medical guidance towards health which is known to be desirable, economically practicable, and productive of a very tangible degree of life saving.

It remains primarily for the physician in private practice to persuade his families of the value of prenatal supervision.

It is to the pediatricist, however, that public health owes its largest debt of gratitude, for it has been to his credit that the healthy babe put in his trust at birth has received increasingly complete health service, whatever the economic status of the parents, until the child is by law at liberty to engage in self-support and escape the application of compulsory education.

No single element in the advance of preventive medicine has contributed so much to the increase in average expectancy of life, to the prevention of

infant mortality, and the reduction of many of the communicable and nutritional diseases of childhood, as has the introduction of health supervision, as a function of the ordinary personal or family practice of medicine, and into the routine of organized public health work.

In infancy, during the pre-school age, and for school children it is now usual to provide, at public expense where necessary, but to an increasing degree through the family physician or the child specialist, a supervision of growth and development, the establishment of at least two specific active immunizations, and medical and dental health examinations, at appropriate intervals, not for the purpose of detecting disease but with the object of establishing and maintaining life, and its most important functions in childhood, growth in physiological equilibrium, together with avoidance so far as may be of communicable diseases, and developmental defects. We know now that where our city communities are alert to use and supply health services for children, of those from two to five years of age 75 per cent or more have at least an annual medical examination, 30 per cent have a dental examination, 35 per cent to 50 per cent are vaccinated against smallpox and about 50 per cent are known to be immune to diphtheria. In no community are these four measures compulsory for pre-school children and it is to be hoped they never will be. In but few are any but smallpox vaccinations required for children entering school. The influence of the medical practitioner and his associates is seen at its best in that field of preventive medicine where

there will probably never enter the authority or obligation of law or ordinance. No advocacy of health measures is listened to with the respect accorded to the family physician's voice.

Each specialty of medicine and surgery has awaiting it a field of effort similar to that so vigorously cultivated by the obstetrician and the pediatrician. The orthopedist, ophthalmologist and neurologist share with the dentist, the internist and the dermatologist a responsibility for guiding the public towards health by appropriate personal persuasion and example.

The success of each organized effort for control or prevention, whether directed against tuberculosis, syphilis, cancer, diabetes, emotional catastrophe or blindness, has been created in the relationship between physician and patient in which the former matches his skill, his imagination, his physiological acumen against the probability or significance of sub-clinical manifestations of disease, or his knowledge of the usual results of disorderly or immoderate ways of living.

The individual physician can rarely accumulate sufficient personal experience with disease, or the variable conditions under which health occurs, to avoid a high degree of probable error in his conclusions as to the relation between cause and effect of personal habits, over weight, under exercising, short sleeping, too much, or disproportional eating and drinking. He needs must rely up on massed experience, and learn to apply other people's assembled facts to the individual man or woman before him. He must learn that there are at least as many ways of healthy

living as there are kinds of disease, and that the essence of his particular privilege is attaining the optimum of health, not the mediocrity of average health, or the mere negative success of freedom from disease, for the client who seeks his guidance.

We have attempted through government great accomplishments in mass prevention of disease. There are now incorporated into our social order functions which could under no safe conditions be trusted to the individual or to the family. We pay perhaps a half dollar, at most a dollar and a quarter, often not more than 25 cents apiece each year to secure the administration of public service for health. Of this about a cent and a half a year goes for the registration and analysis of births and deaths, 8 cents for communicable disease control other than hospital care, 4 cents for tuberculosis, and a cent and a half for venereal disease control, the price of half a glass of milk, 3 cents, to guarantee a tubercle free pasteurized milk supply, as much as five cents apiece for the safety of maternity and infancy, thirteen cents for school health, a trifle of ten cents for food and environmental sanitation, four cents for laboratory work, with six cents for administration including health education. And all this is for a rather crude broadcast type of mass protection. And yet how priceless the benefits, how totally has the outlook of man and his wife and child been altered by even this wholesaling of health. In Philadelphia in 1929 the per capita cost of medical care of all kinds was \$52 of which about two dollars went for prevention. The people of an average midwest rural county

spend \$22 per capita each year, of which about 2 per cent is for health. The health officer must operate his specified services under the limitations imposed by partisan politics and insecure tenure of office, by restricted funds, by the tardily advancing common sense of the populace, and he sees much ahead which he can do to improve water, milk, public understanding, immunity, and physical environment, but even the ablest and best supported, the honest and fairly permanent commissioner of health of state, county or city will quite frankly declare, or admit if challenged, that his potentiality for good is but a fraction of what can be the certain result if physicians in private practice were to enter with as much determination upon health guidance, as they now devote to disease detection and repair.

The future of preventive medicine, the adding of the next and most difficult ten years to the expectancy of life, awaits the universal participation of the practitioner of personal medicine and his patients in the practical use of our abundant knowledge of health development and protection.

It will not be by compulsion or ordinance that the obese, arteriosclerotic, diabetic, or cancer patient will begin to decrease among us, or survive into the allotted seventies, but by such universal voluntary self-interest in health and the management of the later decades of life as will permit the detection of pre-clinical signs and symptoms which may lead to prevention by minimal changes in the conduct of life, without the panic fear of late inevitable disclosure of advanced irremediable disease. Only through the words of the family physi-

cian trusted in birth, sickness, and death will parents and other men and women be persuaded to legitimate and persistent interest in health, and this only when the example of the physician toward his own family and dependents carries conviction of his sincere belief that personal medical practice is capable as much of advancing individual health as it is of relieving and sometimes curing disease.

The influence of the practitioner of medicine in guiding the public towards health is as yet unevenly applied, doubting, almost scoffing, except for the beginning periods of life and growth. It is capable of benefits, to a degree so far surpassing the possibilities of public health agencies, as to justify criticism that it is too timidly conceived.

Constructive nurture often assumed under modern medical statesmanship to be the province of public health becomes effective only when it has lost the implication of generalities and assumes the character of personal guidance by the practising biologist of today's society, the family physician. To quote from a recent article by Lord Dawson of Penn, "The more the cost of social policy is centralized, the farther its administration removed from the man who receives the benefit, the more apt is that man to lean upon a prop, to become a creature of fate rather than a master of effort." The influence of the family physician is at its best when it activates the individual to acquire health by the exercise of his own character, to prove to himself that health is a by-product of initiative and effort.

We have adapted ourselves more ef-

fectively to our zoological enemies than to the successes of our material prosperity and the mechanization of today's existence

Are we not committed by our professional philosophy to that third gospel as Dr Osler described it. "The gospel of his body which brings man into relation with nature, a true *evangelion*, the glad tidings of a conquest beside which all others sink into insignificance, the final conquest of nature, out of which has come man's redemption of man"? Whether we dream with Plato or fling out the challenge with Dr. Holmes—the temper of thought remains the same. Plato looked to the day "when our youth will dwell in a land of health and fair sights and sounds, and receive the good in everything, and beauty, the effluence of fair works shall flow into the eye and ear like a health giving breeze from a purer region and insensibly draw the soul from earliest years into likeness and sympathy with the beauty of reason "

Dr Holmes, in addressing the predecessor of our present public health association in 1860, foretold the chang-

ing emphasis from curative to preventive medical practice, and gave prophesy to the thoughts of today in the following stanzas

"What though our tempered poisons
save

Some wrecks of life from aches and
ails:

Those grand specifics Nature gave
Were never poised by weights or
scales!

God lent his creatures light and air,
And waters open to the skies;
Man locks him in a stifling lair
And wonders why his brother dies!

In vain our pitying tears are shed,
In vain we rear the sheltering pile
Where Art weeds out from bed to bed
The plagues we planted by the mile!

Be that the glory of the past;
With these our sacred toils begin:
So flies in tatters from its mast
The yellow flag of sloth and sin,

And lo! the starry folds reveal
The blazoned truth we hold so dear
To guard is better than to heal,
The shield is nobler than the spear!"

The General Practitioner and the Public Health Program*

By FELIX J UNDERWOOD, M D, F A C P, *Jackson, Mississippi;*
President, Southern Medical Association

IT IS to the credit of our profession that its members have interested themselves actively in good government, and especially in those functions that have to do with the physical well-being of man and that involve applications of medical art and science both in the prevention and the cure of the diseases which afflict mankind

There is not a single point at which public health and private medicine cannot march forward in peace and good will. Our profession is traditionally committed to the prevention, as well as the cure, of disease. Out of its early labors arose the first slender shoot of this magnificent tree of health that is beginning to bear good fruit today. From its membership have come our foremost public health leaders. Be it said to the everlasting credit and to the honor of American physicians that they are watering, fertilizing, and protecting this tree of life in the midst of the garden of our united effort against the insects and poison bugs of ignorance, superstition, and of rampant quackery which establishes so-called health institutes, health homes, adver-

tises so much about your health and often puts it over on a gullible uninformed public and yet knows little or nothing of medicine, either curative or preventive, notwithstanding the fact that they pose as physicians and talk glibly and advertise freely to prevent and cure all diseases which afflict the race. They bitterly oppose the principles and practice of preventive medicine, denouncing immunization and vaccination. They profess not to believe in the germ theory of disease yet so ignorantly inconsistent are they that most of them now tell people that immunization and vaccination cause many diseases such as syphilis, typhoid fever, meningitis, and within this week I have had otherwise intelligent people call me and tell me what "doctor quack" said about it.

Do we need a consistent, persistent program of health education and demonstration backed up by the physician one hundred per cent for the enlightenment and for the protection of our citizenship in every county, in every community, in every home, and with every individual in our State? Do we? Health education like Christian education is a real job in this day and time when evil forces are presenting

*Delivered at the Baltimore Meeting of the American College of Physicians, March 24, 1931

a united front We must stand united in our efforts or we fail miserably.

The most obscure physician gives some portion of his energies to the conservation of health and usually lends his voice in support of public health measures.

Lack of information is a universal fomenter of strife For the physician disciplined in diagnosis and therapeutics, the private relationship between patients and practitioner circumscribes his horizon. That medicine also fills a public relationship, in which the good of the individual may frequently be submerged by the greater welfare of the group, is outside the compass of his vision. He is unwilling to admit that a mass of information and a technique have grown up within the realm of preventive medicine and sanitation that are generally ignored in our medical schools, yet are just as valid as the subjects regularly taught The smattering of so-called "hygiene and public health" that was forced on him in student days appears to him to comprise all that is or needs to be known Every health officer is acquainted with private practitioners who freely admit their ability to fill any public health position with distinction with no previous training. A mind that is permanently closed to new knowledge in other spheres than its own will discount all such new ideas as negligible or subversive of the regular order. Even the physician with a reasonably flexible mental apparatus is often amazingly uninformed of the first principles in preventive medicine and sanitation, a field so closely allied to his own that curiosity alone would seem to compel superficial acquaintance Out

of this lack of information grows resentment toward even the simpler routine procedures of common sanitary practice. An attitude is created which evinces itself in unthinking resistance to all that bears the label of public health Fortunately, this inertia is not often found among physicians

However, not all of the blame is on one side. The public health worker must share some of it, for he fails many times to make any effort to enlighten the physicians within his field as to his plan and methods A full explanation, at the outset, would usually convert medical opposition into acquiescence, at least, if not hearty support His first duty is to educate the doctor, for we are all laymen outside our own specialties In this, as in every succeeding step of his program, the utmost tact is essential Painful memories rise to haunt the health executive who has had under his direction any number of workers. He has seen, more than once, an initially friendly group of medical men turned into enemies of the entire health program through rudeness, arrogance, superciliousness, bad temper, or lack of public health training on the part of a new worker The medical profession has suffered much at the hands of such as these Unsound judgment in selecting a project, or offensive methods of promoting it, will also alienate friends

Of one cause of medical opposition, selfish, mercenary motive, the less said the better. But all experienced health officers have felt its force. The physician of this caliber is so frequently aggressive and "successful" that he holds an influential position in his com-

munity By underground methods he can defeat an honest, well considered project without revealing his hand That he fears the specter of diminished business is simply evidence that his selfishness is matched by his ignorance, for the real all-time well trained health officer is a press agent of scientific medicine Or this kind of physician may covet a place on the public payroll for the money or the publicity to be had out of it In any case his personal gain is made to transcend the public welfare

We who hold positions with the government are always under some suspicion—a suspicion that seems to be growing stronger of late, that is taking the form of a great fear, fear of ultimate domination over all life by an autocracy of bureaucrats Perhaps some of this suspicion is deserved Dictatorial, grasping, impractical, politically partisan persons are found in health departments as in other branches of the government To inject a degree of humanness into an office crowded with necessary routine, to retain a sensitive awareness of the multifarious viewpoints in a large constituency, is no sinecure Yet the more successfully it is done, the more fully will needless suspicion of governmental agencies be overcome It is a paramount duty of all public health executives

Granting, then, that there is sometimes divergence of interests between public and private medicine, where there should be convergence, that there is antagonism where there should be accord, it will be profitable to consider its effects They will manifest themselves in two directions retardation

of sanitary progress in many quarters, and a growing distrust of the medical profession on the part of the public Enough examples have been given earlier to clarify the first point, that lack of medical support, or active opposition, will delay legitimate public health developments But the effect of this attitude on the lay mind may not be so evident to the private practitioner To the medical health officer, standing midway between him and the public, a view in both directions is possible He catches a sense of frustration and of growing exasperation among the laity, that is not revealed to the family doctor so freely He finds the public demanding more service, while his medical colleagues criticize what is already given He realizes that the public is often more fully "sold" on the health program than is the profession His dilemma is sometimes acute As a public servant, his duty is to do the public's will Yet, if he accedes, it will bring to light the reactionary tendency of the medical group He feels himself a Judas among his brethren If such a crisis arises, as it has repeatedly, the layman develops a distrust of the physicians, he is openly critical of their motives and his resentment is likely to be extreme Are not the proposals for health insurance partly the result of just such a process? Are they not the grasping of the public after some method whereby the benefits of curative and preventive medicine may be made available to all, and at once, without waiting for the medical profession to arrive at a broader social outlook? This is not the sort of thing that the great body of health workers

desires, but it is a very natural reaction of enlightened public opinion. "Phantom" this public opinion may sometimes be, but it is a ghost that takes on substance as it gain momentum.

If the discussion so far is a correct interpretation of trends, some solution is sorely needed. Not that we may hope to change human nature, if the fault lies there, but that we may try to bring about more intelligent understanding on both sides and a resultant solidarity now lacking.

Beginning with his earliest medical training, the student should be made to see how his subjects are related to public health. In bacteriology he can learn the uses and duties of state and city laboratories, the methods pursued by them and interpretation of their reports. Lecturers on practice of medicine ought to lay more stress on sources and modes of infection, on ordinary control measures and on the duty of the private physician to protect the community as well as his patient. Courses in pediatrics open the way to the whole field of child hygiene, while obstetrics holds the same relationship to prenatal and maternal hygiene. Medical jurisprudence embraces legal aspects of the practitioner's public health functions. And, lastly, the course in preventive medicine, hygiene, and sanitation should be the point at which these strands are woven together; where the embryonic doctor sees the whole public health field, and comprehends the fact that he has a prominent and inescapable position in it. Do we have such correlation in our medical curriculum today? Hardly. Most of the men who are teaching major sub-

jects in the schools are themselves lacking in this vision. Can more be expected of the people, when their leaders fail?

The medical practitioner has a real place in the public health field. As a matter of fact, preventive medicine is going to consume an even greater proportion of his time. This does not mean those ordinary things that are expected of every conscientious doctor, such as early reporting of morbidity and of births, administration of prophylactic biologic preparations, efforts to protect the community against the infection of his patient, and occasional help in various clinics for the indigent. These he does now to a greater or less degree. But preventive medicine has taken on a broader meaning in recent years. There has come a realization that humanity can be made healthier, and happier, by the early detection and correction of minor deviations from normal, than by curative measures applied after these conditions have produced gross pathology. "Positive health" is as good a name as any for this new objective. And the family doctor is its prophet. Better than anyone else, he can, if he will, make the next generation more fit than its predecessor. This calls for a personal relationship that no governmental agency can so satisfactorily provide. Opportunity is in the making for the private practitioner to take his own peculiar place in the public health movement. Technical preparation there must be, exactly as one would fit himself for any other special procedure. A new approach, a new viewpoint, must be acquired. He is dealing with a well man who wants to keep well.

The health officer prepares the way by education and the physician should make ready for the future that lies in that direction. The American Medical Association has repeatedly endorsed this program. Likewise, state and county societies here and there have caught the meaning of it. But until the man in general practice makes it a real part of his everyday business, it will remain only a pleasant topic of conversation. This is the challenge of the sanitarian to the private practitioner.

Wrapped up with these matters that have been touched on are problems of the medical profession far more profound and significant. What does it mean that there is an active demand in some quarters for a kind of state medicine? Why do we see such contemptuous disregard for the fine fruit of scientific medicine, while any new and blatant cult receives enthusiastic welcome? Opposed as these two trends may seem on the surface, they arise from a common source: lack of socially minded leadership within the

profession. Broadminded, strong, resourceful leaders can point the way and can knit our individualistic membership into a well coordinated group for the solution of these difficulties. Without that, we may have forced on us a ready-made scheme of social medicine.

In other words, the public wants and demands a complete program of health and healing, of which every individual may have the benefit without undue sacrifice, and it is going to have its way somehow. We have the requisite knowledge and skill. Are we intelligent enough to cooperate in meeting this need with a plan of our own devising?

This may seem far removed from the subject of "The Relationship of the Private Practitioner to the Public Health Program," but it is not. That relationship is merely an expression of his outlook on life. The keener our sensitiveness to human need in the aggregate, the brighter will be the hope of fulfilling our ultimate destiny as a profession.

Editorials

EDITORIAL POLICIES

That there will be no abrupt change in those editorial policies under which the *ANNALS* has prospered so greatly, it is needless to state. The present editor has been in close touch with the development of this journal during the past seven years and is fully in accord with the general plan of its organization and production as it has been evolved during that period. He will constantly strive to make the *ANNALS* representative in the highest sense of the American College of Physicians of which it is the official organ. He believes that this can best be done by continued emphasis upon the quality of its scientific articles in order that they may represent, in so far as is possible, not only the most advanced but also the most mature, medical opinion of the times. To this end he invites the submission of manuscripts from both non-members and members of the College and promises that careful consideration will be given to all. Since there are certain fixed limitations upon the size of the annual volume, selection of the most useful material must be made and authors whose manuscripts are returned to them are urged to bear in mind that there are other considerations than the actual worth of the subject matter of a communication which may lead to its rejection. It may deal with a field which is not of

interest to a large number of the readers of the journal; it may treat a subject in too extended a manner to be suited to the size and spirit of the *ANNALS*; the same subject may have been discussed in a recent number, or another paper covering the same ground may have been accepted but not yet published.

In general, the freedom in respect to diction and style which has been allowed authors in the past will be continued. No effort will be made to develop uniformity of expression at the cost of individuality. The editorial pencil will seldom be used except to correct verbosity and ambiguity. However, in the interests of better appearance, greater economy in production and heightened usefulness, the bibliographic references are to be standardized within certain limits. Brief directions in regard to the form desired may be found on the back cover of each number.

In order more fully to represent the broad interests of the American College of Physicians it is hoped to place upon the editorial pages rather frequently communications from those whose special interests, training or experience give their opinions authoritative weight. Such contributed editorials will be initiated to differentiate them from those for which the editor is alone responsible.

CARBON MONOXIDE DEATHS

Litigation based upon the circumstances attending carbon monoxide, and particularly 'garage', deaths is constantly increasing. Physicians should exercise great care in certifying to the cause of death in such cases. The question which usually arises is as to whether death was accidental or suicidal. Since investigation of possible motives, of the behavior of the deceased in the last few hours or days of his life and of all of the minute details of the surroundings amid which the body was found may be necessary for reaching a decision, it is evident that the physician who answers an emergency call and determines that death has occurred cannot be expected to pass final judgment upon the question of accident or suicide at the moment. Unless he is himself a coroner or coroner's physician it should not be his duty to do so at any time, but the family of the deceased may look to him for an opinion. There have been numerous instances in the last few years which make it evident that knowledge of 'garage' deaths is so generally disseminated among intelligent laymen that not infrequently the stage is elaborately set to conceal the fact of suicide. This is especially apt to be true when a man carrying heavy accident insurance, or recently insured under a policy with a suicide clause, and in serious financial straits, plans to take his own life in such a manner as to improve the financial position of his family. Tools may be scattered about, oil or grease applied to hands

or clothing, the hood of the car raised, and the body found in a position consistent with repair work or adjustment of some part of the motor.

Another difficulty which has arisen attaches to the use of the word 'poisoning' in connection with carbon monoxide deaths. The phrase 'carbon monoxide poisoning' has become fixed in medical parlance, but in a recent instance a Circuit Court Judge dismissed a case in which it was sought to secure compensation for a carbon monoxide death under an accident insurance policy in which there was a clause setting forth that no liability existed for death from poisoning. The deceased was found dead in his garage and the question of suicide was not raised by either party to the issue. Certainly the non-medical use of the term 'poisoning' in such a policy, and in all probability the understanding of it by both the vendor and purchaser, should not have been such as to exclude accidental death from inhalation of carbon monoxide from compensation. If such rulings stand unchallenged they will prevent compensation for a large group of undoubted accidents in which toxic agents are instrumental in producing injury and death. In the instance in question the trial judge was entirely satisfied by the fact that death had been certified to as due to carbon monoxide *poisoning*. Physicians may be forced to adopt some such circumlocution as 'death from inhalation of carbon monoxide', and the phrase *asphyxia carbonica* is justified by long usage.

SPONTANEOUS RUPTURE OF THE SPLEEN IN INOCULA- TION MALARIA

While traumatic rupture of the spleen from falling from a height and from contusion and compression of the abdomen is relatively common, spontaneous rupture has always been a rare condition. It has been known to occur in typhoid fever, typhus, recurrent fever and occasionally in accidentally acquired malaria. All of these conditions have in common the possibility of a rapidly developing splenic tumor through congestion and lymphoid hyperplasia. In ordinary malaria, however, spontaneous rupture of the spleen is a very rare complication. It is said to have occurred but three times in 30,000 cases of malaria observed during the building of the Panama Canal. A number of authors leave the impression that in inoculation malaria for the treatment of paresis a splenic tumor seldom develops, but that splenic enlargement can occur and may be so marked as to produce spontaneous rupture has been shown by several cases. Jutz and Jacobi (*Munch med Wchnschr*, 1931, lxxviii, 395-396) describe an example of this accident which they claim to be but the third to be reported as occurring in the course of the treatment of paresis in which there was no question of the spontaneous nature of the rupture. Their patient was a tabo-parietic, thirty-nine years old who had been inoculated with malarial blood twenty-three days before. He had reached his seventh cycle of a typical malaria, each with a fever of 104 degrees or above, when he suddenly went into a state of collapse with coma, pallor, rapid shallow

breathing and a feeble pulse which soon became imperceptible, death following within a few minutes. There had been no possibility of trauma. At autopsy a hemoperitoneum of two liters was found. Hemorrhage had occurred from a rupture of the greatly enlarged spleen, the tear reaching from the lower pole nearly to the hilus. After bleeding out, the spleen still weighed 540 grams. An entirely similar case came to autopsy in the Department of Pathology of the University of Michigan several years ago. This patient, under malaria treatment for tabo-paresis, had successfully completed thirteen chills during which the temperature ranged between 100 and 104 degrees. Following his fourteenth paroxysm he suddenly became dyspneic, vomited profusely and his pulse rose to 150, death following almost immediately. At autopsy the peritoneal cavity was found to contain over two liters of fluid blood and blood clot. The spleen weighed 580 grams and its upper pole was covered by a large mass of blood clot beneath which there was a rupture of the capsule and eversion of the soft pulp. When the rather limited application of malaria therapy is considered, it seems not unlikely that rupture of the spleen is more apt to occur in this group than in those having naturally acquired malaria. The reasons for this can only be surmised. It would be important to learn if those dying from rupture of the spleen in acquired malaria show a higher incidence of syphilis than the entire group from which they come. Can rupture of the malarial spleen in the syphilitic be attributed to changes in the supporting stroma, a loss of elasticity perhaps,

as part of that 'Derbheit' which gross pathologists recognized more than a generation ago? Or is the cause to be sought in cardio-vascular changes, due to which the splenic congestion of malaria is imposed upon a preceding con-

gestion of luetic origin? At any rate, the occasional occurrence of this accident is an added argument for investigating the efficacy in the treatment of progressive paralysis of other agents capable of inducing hyperpyrexia

Abstracts

Occurrence of Numerous Large Giant Cells in the Tonsils and Pharyngeal Mucosa in Prodromal Stage of Measles By ALFRED SCOTT WARTHIN (Arch of Path, 1931, xi, 864-874.)

This paper, which appeared posthumously, describes an entirely new histopathological feature of the prodromal stage of measles. In four instances, in the course of the examination of about 50,000 pairs of tonsils, there were found a subepithelial infiltration of multinucleate syncytial giant cells, lymphocytes and monocytes, wandering of the giant cells into the mucosa and on to its surface, with edema and congestion, marked lymphoid exhaustion of the germinal centers with production of the multinucleate giant cells from cells of the lymphoblast type and migration of these cells toward the mucosa. In the first patient, two days after tonsillectomy there was a temperature of 102.5° F, coryza, mild conjunctivitis and Koplik's spots. Two days later the fully developed eruption of measles was present. As a result of this experience, when similar giant cells were found subsequently in the tonsils of two other patients, the onset of measles was correctly predicted in advance of any clinical manifestations. In a fourth case, which had been examined without history four years before, a diagnosis of measles was then made, and enquiry brought the information that the patient developed measles on the day following tonsillectomy. These four pairs of tonsils were the only ones in the entire series which showed such giant cells and, as far as known, there were no other instances of prodromal measles in this material. Thus it appears that this pathology is so distinctive that a positive diagnosis of measles can be made from one to five days before the exanthem appears. The process is interpreted as a defensive one, indicating the presence of an etiologic agent, either in or on the pharyn-

geal mucosa, but the application of a large variety of staining methods failed to show micro-organisms either in the multinucleate giant cells or in neighboring structures.

Shadows Produced by Lead in the X-Ray Pictures of the Growing Skeleton By EDWARD A. PARK, DEBORAH JACKSON and LASLO KAJDI (Am Jr of Diseases of Child, 1931, vi, 485-499)

It has been known for some time that the administration of phosphorus to growing children causes the freshly forming trabeculae at the ends of the shafts of the long bones to multiply and become closely packed together, thus producing a dense shadow. After the administration of phosphorus has been suspended for the proper length of time this shadow takes the form of a band which appears displaced toward the shaft since the most recently formed bone at the extremity of the shaft is less dense. In four cases of chronic lead poisoning studied by the authors similar shadows were found, although the bands were not so broad or so striking as those obtained by means of phosphorus. In two fatal cases in young children the shadows were narrow and intense. From this it might be inferred that the period of poisoning was relatively short and the amount of lead ingested large. In the third case the shadow was broad and extended to the cartilage which would indicate that the poisoning had continued to the time of the patient's admission to the hospital. The shadows in the bones in the fourth case were not as intense as the history might lead one to expect but their breadth (1 to 1.5 cm) was in keeping with the known long duration of poisoning, and their position just under the cartilage was in accord with the fact that the eating of lead had continued up to the time when the pictures were taken. It is highly probable that the cloud, as described, can occur only in young and growing bones.

and therefore will be the more strikingly developed, the younger the subject. The normal shadows in a child one or two years old or older must not be mistaken for those produced by lead.

The Localizing Significance of Impaired Respiratory Movements in Lesions of the Spinal Cord By WALTER O KLINGMAN (Bull. of the Neurol. Institute, New York, 191, 1, 136-144)

Information of great value in localizing motor lesions involving the spinal cord may at times be obtained by careful observation of the action of the muscles of respiration. Due regard must be given to non-neurological affections in the thorax which might modify the action of the intercostal muscles and diaphragm. Five groups of variations which are of neurological import are recognized. The *first* group shows exaggerated lateral movements of both costal margins and includes the cases of paralysis of the diaphragm, such as may occur in poliomyelitis and other lesions of the second, third and fourth cervical segments due to syringomyelia, syringobulbia and occasionally infectious myelitis. In the *second* group the entire costal margin of one side moves farther and more promptly in a lateral direction. This indicates a paresis of the diaphragm on the involved side, such as may occur in syringomyelia, localized poliomyelitis and disease of the phrenic nerve. The *third* group exhibits a symmetrical movement of the costal margins of both sides toward the median line and is seen in transverse lesions of the lower cervical and upper thoracic cord, and to a less extent in low lesions of the thoracic cord which interfere with the innervation of the lower six intercostal and the posterior serratus muscles on both sides. The *fourth* group, in which the costal margin of one side moves toward the median line, results from paresis or paralysis of the lower intercostals on the involved side. The costal margin may flare laterally on the opposite side. This has been of value in determining the upper limit of the lesion in acute poliomyelitis. The *fifth* group shows, in addition to the exaggerated lateral

movements of the costal margins, an inspiratory retraction of the upper ribs and manubrium. This occurs with paralysis of the scaleni and upper intercostal muscles and has been observed in the terminal stages of myelitis.

The Specific Therapy of Pneumococcus Type I and Type II Pneumonia By HORACE S BALDWIN (Am. Jr. Med. Sc., 1931, clxxx1, 788-796)

During the four winters of 1926 to 1930 a controlled test of the value of specific therapy in pneumonias due to pneumococcus Type I and Type II has been conducted at the New York Hospital. Patients were assigned to two series in numerical sequence thus establishing an equivalent control group. The concentrated solution containing antibodies for Type I and Type II only, prepared according to the method of Felton, was used. The results were as follows:

Untreated Control Series			
Type	Cases	Died	Per Cent Mortality
I	20	5	
II	29	15	
	—	—	
	49	20	40.8
Treated Series			
Type	Cases	Died	Per Cent Mortality
I	19	1	
II	35	9	
	—	—	
	54	10	18.5

The administration of concentrated immune bodies to these patients was found to be relatively free from dangerous reactions and serum sickness, so that it was possible to give large amounts within a short time. The favorable clinical effect observed seemed to be due largely to the limitation of bacteremia. These results point to a definite advantage derived in specific therapy of Type II pneumonia, hitherto a discouraging procedure, when concentrates of high unit value are given in large amount.

Cinchophen Poisoning By T. P. CHURCHILL and F. H. VAN WAGONER (Proc Soc. for Exp Biol and Med, 1931, xxviii, 581-582)

When rapid cinchophen poisoning was induced in dogs by the administration of 27 times the human therapeutic dose, the animals refused to eat after from two to ten doses had been administered and died in from 9 to 20 days. The blood urea nitrogen first showed a marked rise, followed by a depression before death. The bromsulphalein test showed increased retention of the dye when the urea nitrogen decreased. In certain of the animals acute gastric ulcers were found at autopsy and all exhibited varying degrees of liver damage, from small areas of coagulation necrosis just beneath the capsule to complete disappearance of liver cells in small areas. Two dogs, which had been prepared 11 months before by the production of kidney damage by interference with the renal blood supply, were fed the usual human therapeutic dose of cinchophen, i.e., 22 mg per kilo of weight. The urea nitrogen showed a slight rise, then a slight decrease as the bromsulphalein retention increased. The bromsulphalein test indicated an increasing retention with fluctuation in degree until two feedings were missed when a drop occurred. These dogs survived.

Age Incidence of Communicable Diseases in a Rural Population By EDGAR SYDENSTRICKER and SELWYN D. COLLINS (Public Health Reports, 1931, xli, 100-113)

The United States Public Health Service, with the cooperation of the Milbank Memorial Fund and the county health department has been conducting epidemiological studies in Cattaraugus County, New York, since 1929. The reports of certain communicable diseases for the preceding period, 1925 to 1929, have also been investigated. These data have been divided according to age, and also according to type of locality, as follows: (a) Cases occurring in Olean, a city of about 22,000, (b) in villages of not over a few hundred population, (c) among persons living on farms, designated as "rural." Measles, scarlet fever and whooping cough were the diseases investigated particularly. It was found that, with hardly an exception, the more rural the population, the higher were the ages at which these diseases occur. In the Olean group there was a marked tendency for a relatively high concentration of these diseases at the ages when children enter school, while in the rural group the risk of attack was more uniformly spread through the ages of childhood and adolescence, and the peak of the curve of incidence came distinctly later in childhood.

Reviews

Practical Treatise on Diseases of the Digestive System By L WINFIELD KOHN, M D, F A C P, Formerly Assistant in the Gastro-Intestinal Clinic, Johns Hopkins Hospital, Baltimore, Chief of the Clinic of Gastro-Enterology, Medico-Chirurgical College, Philadelphia, etc, Present Chief of the Gastro-Intestinal Clinic, Lebanon Hospital, New York City, etc Two volumes, xx + 574, and x + 555 (575 to 1,125) pages, 542 illustrations including 7 colored plates F A Davis Company, Philadelphia, 1930 Price for two volumes, \$12.00 net

Until one surveys the field of essential subject matter that must be included in a treatise on diseases of the digestive system there can be but little realization of the task which confronts the author who attempts such a work. The reviewer might be inclined to be critically disposed when he finds in the present work but a page given over to typhoid fever and only a line to acute poisoning with lead, mercury and arsenic, did he not realize that the entire range of diseases of the alimentary tract, from xerostomia, through the avitaminous diseases to carcinoma of the rectum and hemorrhoids was clamoring for representation. The first chapter is a brief presentation of anatomy of the digestive system, while the second covers the physiology of digestion in 64 pages. The eight chapters which follow give the methods of clinical approach and investigation. Here roentgenological methods receive the most complete discussion, with nearly 100 pages devoted to this division. The author's interest in intragastric photography is shown by a detailed description of the gastro-photor and its uses. Nine pages are given over to reproduction of such photographs. The diseases of the various portions of the digestive system are next taken up in anatomical order and the second volume is brought to a close with chapters

dealing with gastro-intestinal parasites, gastro-intestinal symptoms produced by diseases of other organs, dietary considerations, therapeutic considerations, and a brief discussion of surgery of the gastro-intestinal tract. Brief bibliographies are added to many chapters. This work is very well printed, containing remarkably few typographical errors for a first edition and the division into two volumes adds greatly to convenience in handling. This practical treatise will appeal primarily to physicians engaged in general medicine.

Abdomino-Pelvic Diagnosis in Women By ARTHUR JOHN WALSCHEID, M D, Director of Obstetrical and Gynecological Department of Pan-American Medical Center and Clinics, New York City, Consultant in Gynecology and Obstetrics to Margaret Hague Maternity Hospital, Jersey City, N J, Consulting Gynecologist to Bergen County Hospital, Ridgeway, N J, Consulting Gynecologist to F Reuter Home, North Bergen, N J xxiii + 1,000 pages, 397 illustrations and one color plate. The C V Mosby Company, St Louis, 1931 Price, \$12.50

This work deviates considerably from the usual style of treatises on gynecology. It is strictly limited to the diagnostic field and omits detailed descriptions of normal physiology and anatomy on the one hand, and of operative procedures on the other. It develops the subject along broad anthropologic lines, the author freely acknowledging his debt to Professor Jayles' *Morphology of the Human Female* for this portion of his material. Throughout the entire book this interest in the biological and particularly the psychological phases is apparent. Perhaps the bread-and-butter gynecologists, if there are such, will be disappointed in this method of treatment, for the book must be read with understanding to be appreciated.

The first four chapters, 351 pages, deal with general gynecology, the remainder of the work in ten chapters treats special gynecology, taking up the respective disease conditions in order as determined by anatomical considerations. This section of the book gives less space, relatively, to some of the common, well understood, diseases, and is especially valuable for the completeness with which the less common conditions are treated. The pathologic interpretations are sound and in accordance with the best opinion. A more extended review of this work would be inappropriate for the *ANNALS*. It merits the fullest approval and is especially commended to those who believe that Medicine is, after all, a biological science.

The Treatment of Asthma By A. H. DOUTHWAITE, M.D., F.R.C.P. (Lond.), Assistant Physician, Guy's Hospital, Physician in Charge of Massage Department, Guy's Hospital. viii + 164 pages. William Wood and Company, New York, 1931. Price, \$2.50, net.

The preface of this book states that it is hoped that it presents in an assimilable form all facts and theories of practical importance which are relevant to the subject. Most readers will feel that it falls far short of this goal. One is not led to expect a scientific approach as he reads in the first chapter that the practice of classifying asthmatics according to the apparent etiology or exciting factors is confusing and that such a process really does little to clarify the situation. However, the author does classify causes and his presentation gains thereby. The information presented includes practically none that is new and a bibliography of but 46 items furnishes the list of sources quoted. The discussion of treatment and of the results of treatment is restrained and well balanced. The author is to be commended for his conservatism in refusing to be carried away by any one procedure. Judged by American standards and fashions, this book (printed in Great Britain) is cheaply and unattractively produced. The American purchaser will feel that in respect to both format and content it is overrated.

Physics of Radiology By J. L. WEATHERWAX, M.A., Physicist Philadelphia General Hospital, Associate in Radiotherapeutic Physics, University of Pennsylvania Graduate School of Medicine. 126 illustrations. xviii + 240 pages. Paul B. Hoeber, Inc., New York, 1931. Price, \$5.00.

The older radiologists were able to keep abreast of the development of their subject as their knowledge grew with it in the course of its evolution. For the student who is now entering upon this field of work, the physical problems are far more complex and diversified and the apparatus much more complicated. Without going too deeply into general physics, electricity and mathematics, this textbook presents the necessary information for an understanding of the principles of radiology, the construction of type forms of apparatus, and the general theory of dosage. Thirty-two tables of various constants and other useful information are introduced. The student will find this book of great value in establishing a sound basis of knowledge of the subject. More liberal use of references to the more advanced literature would have been of advantage to the student seeking authority for some of the material presented. The press work is excellent and the binding neat and practical.

Roentgen Interpretation: A Manual for Students and Practitioners By GEORGE W. HOLMES, M.D., Roentgenologist to the Massachusetts General Hospital and Assistant Professor of Roentgenology, Harvard Medical School, and HOWARD E. RUGGLES, M.D., Roentgenologist to the University of California Hospital and Clinical Professor of Roentgenology, University of California Medical School. Fourth edition, revised, xii + 339 pages; 237 illustrations. Lea and Febiger, Philadelphia, 1931. Price, \$5.00, net.

In the interpretation of roentgen pictures, as in the diagnosis of tissue sections, a judgment cannot be made by direct comparison with other pictures or with other slides. Yet such illustrative material may be of very great aid. Each logical process may never be duplicated in respect to all possible details, but the, always of the, can

eral laws. The authors of this manual have wisely emphasized these principles both in their prefatory advice and in the use of a large number of well chosen illustrations. The first chapter is given over to a brief discussion of confusing shadows and artefacts and the second to anatomical variations and rate of development, with tables giving the time of appearance of the various centers of ossification. This is followed by the pathology of the bones and joints, of the organs of the chest, gastro-intestinal tract and genito-urinary tract. The final section is on fluoroscopic technic. The book is fairly well indexed. The treatment of certain subjects seems inadequate in view of their relative importance. Bronchogenic carcinoma, for instance, is disposed of in one-half page and the discussion starts with the usual statement of the preceding generation of texts, that 'primary malignancy of the lung is rare'. On the whole, however, this book can be heartily recommended. Its careful reading cannot be other than stimulating to the young roentgenologist and to the general practitioner.

Practical Radiation Therapy. By IRA I. KAPLAN, B.S., M.D., Director, Division of Cancer, Department of Hospitals, New York City, Attending Radiation Therapist, Bellevue Hospital, Lecturer in Radiation Therapy, New York University and Bellevue Hospital Medical College, Director, New York City Cancer Institute with a chapter on *Applied X-Ray Physics* by CARL B. BRAESTRUP, B.Sc., P.E., Radiation Physicist, Division of Cancer, Department of Hospitals, New York City, Physicist to Mt Sinai Hospital, New York City. 354 pages, 227 illustrations. W.B. Saunders Company, Philadelphia and London, 1931. Price in cloth, \$6.00.

Chapters on the history, definition and action, and production of x-rays and radium form the introductory material of this book. The last mentioned chapter contains numerous interesting photographs, which are not, however, apropos to the main thesis of the book. Applied x-ray physics then furnishes the necessary background for the discussion

of dosage. The remainder of the book is a description of radiation therapy as practiced at Bellevue Hospital. This portion is excellently illustrated and the pictures are largely left to tell their own story as to the various devices to be employed. The reader must constantly bear in mind that this book is not a guide as to *what* method of treatment is to be used in a particular disease condition, but *how* radiation therapy is to be employed provided it is the method of choice. There are many diseases listed, each with its radiotherapeutic procedure, which most physicians would elect to treat by other methods. Such are salpingitis, gingivitis, glandular hypertrophy of the thyroid, pertussis, asthma, vernal catarrh and nasal polyp. One is prone to wonder what pathologic entity was intended when reference is made to a benign fatty tumor of the thyroid (p. 220). This book is well printed, the illustrations are effective. It is sure to be useful to all who are interested in the technical application of radiation therapy.

Microbiology and Elementary Pathology for the Use of Nurses. By CHARLES G. SINCLAIR, B.S., M.D., Major, Medical Corps, U.S. Army, Instructor in Bacteriology, Army Medical School, Instructor in Microbiology and Pathology, Army School of Nursing, Washington, D.C. 362 pages, 102 illustrations, some in colors. F.A. Davis Company, Philadelphia, 1931. Price, \$2.50, net.

The author's experience in instructing student nurses has aided him in selecting for this textbook the essential material and in presenting it in an unusually clear, simple and concise manner. Microbiology occupies 206 pages, Laboratory Exercises in Microbiology, 20 pages, and Elementary Pathology, 103 pages. The last section is perhaps not quite as successful as the others, as it is also the most difficult to present simply to nurses. In each division much skill is shown in the gradual building up of the necessary technical vocabulary, and the presentation is aided by the many well chosen illustrations. This should prove to be a very useful and satisfactory book for the field for which it is intended.

College News Notes

ABSTRACT OF MINUTES OF THE OF THE BOARD OF REGENTS, Philadelphia, Pa., June 9, 1931.

The Board of Regents of the American College of Physicians met at the College Headquarters in Philadelphia, June 9, 1931, with the following present President S. Marx White, Drs David P Barr, Walter L. Bierring, Charles G Jennings, Clement R Jones, James S McLester, James H. Means, James Alex Miller, Sydney R Miller, John H Musser, O H Perry Pepper, George Morris Piersol, Maurice C Pincoffs, Francis M Pottenger, and Mr E R Loveland, Executive Secretary.

President S Marx White spoke briefly about College affairs, referring especially to the death of Dr Aldred Scott Warthin, and the necessity of action by the Board of Regents in providing for the future continuation of the journal, *ANNALS OF INTERNAL MEDICINE*.

The Executive Secretary reported the deaths of nine members since the preceding Regents' meeting, presented special cases requiring action by the Board in respect to fees and dues, and reported in detail the gifts of books and publications presented to the College Library by members, etc. A resolution was adopted providing that Dr. Donald J Frick, of Los Angeles, and Dr. John E Heatley, of Oklahoma City, should be reinstated as Fellows of the College.

Upon the report of the death of Dr. Reynold Webb Wilcox on June 6, 1931, the following resolution was adopted:

Resolved, that the Secretary-General should be instructed to draw up a proper resolution concerning Dr. Reynold Webb Wilcox, in recognition of his being the first President of the American College of Physicians.

Upon report of the death of Dr. Aldred Scott Warthin on May 23, 1931, in recognition of his eminent contributions to the College through the Editorship of the Journal, the following resolution was adopted:

Resolved, that a Committee be appointed to draw up a suitable resolution concerning Dr. Aldred Scott Warthin for publication in the *ANNALS OF INTERNAL MEDICINE*.

Dr. George Morris Piersol, Chairman of the Committee on Credentials, presented the report of his Committee, recommending the election of the following named candidates, who, upon resolution regularly adopted, were elected Fellows of the College.

(The following list is arranged geographically with respect to the candidates elected. Under each candidate's name are listed (1) name of proposer, (2) name of second, and (3) name of endorser.)

Dr Clement R Jones, Treasurer, presented a trust agreement between the American College of Physicians and the Bank of Pittsburgh National Association, providing a means of the bank acting as trustee of the securities of the American College of Physicians, in accordance with a resolution adopted during the Baltimore Clinical Ses-

sion in March. The College has set aside \$50,000 as the nucleus for an Endowment Fund, to which shall be added direct subscriptions for Life Membership, gifts of funds, and bequests in connection with estates. The principal shall be kept intact, and invested in bonds approved by the Board of Regents. By resolution, the Secretary-General, Dr George Morris Piersol, and the Treasurer, Dr Clement R Jones, were instructed to complete the trust agreement with the Bank of Pittsburgh National Association, in accordance with directions and recommendations made by the Board of Regents.

New regulations for the John Phillips Memorial Prize, as printed below, were reviewed, and the following Committee appointed and instructed to proceed in accordance therewith:

James H Means, Chairman, Boston, Mass
David P Barr, St Louis, Mo

James S McLester, Birmingham, Ala
Jonathan C Meakins, Montreal, Que
John H Musser, New Orleans, La

Revised Regulations

JOHN PHILLIPS MEMORIAL PRIZE

- I (a) Interpretation of Internal Medicine—This term should include not only Clinical Science, but, in addition, all those subjects which have a direct bearing upon the advancement of Clinical Science,
- (b) The work upon which this is based must have been done in whole or in part in the United States or Canada
- II Not less than two or more than three members of the Committee should be reappointed each year,
- III (a) The Committee shall appoint Fellows of the College who shall each maintain a close contact with a particular field of the realm of Medical Science and shall report to the Committee any specially meritorious work which has been accomplished in this field,

- (b) If considered necessary or desirable the Committee may appoint a small Board of Referees to visit (at the expense of the College) a particular investigator whose work appears to be of sufficient merit, in order that a first-hand opinion may be obtained by competent observers
- (c) The Committee, after due consideration of the reports submitted by the above appointed Fellows and Referees, may select a recipient or recipients for the Prize and should inform the President of their choice at least two months before the date of the Annual Meeting
- (d) The College reserves the right to make no award of the Prize if a sufficiently meritorious piece of work has not been recommended

IV The recipient of the Prize will be expected to file with the College a written account of his work and to present his results as a paper before the next Annual Meeting after which he will be officially presented with the Prize by the President

- V (a) The announcement of the Prize-Winner will be made not later than two months before the Annual Meeting of the College
- (b) The Executive Secretary shall inform the recipient of the Prize that the College would be pleased to defray his transportation expenses when he attends the Annual Meeting to receive the Prize

President White reported upon arrangements being made for the General Program of the San Francisco Clinical Session to be held April 4-8, 1932. As President of the College, Dr. White is responsible for the preparation of the program of the General

Scientific Sessions. Dr. White reported that he had asked Dr. William J. Kerr, of San Francisco, Dr. Noble Wiley Jones, of Portland, and Dr. F. M. Pottenger, of Monrovia, in conjunction with other men, to act as an Advisory Committee and give names of the men from the far West whose work is desirable for presentation. As a result, a large amount of excellent material has been offered and will be used to make up a considerable proportion, less than half, of the program for the General Sessions in San Francisco next April. Dr. White reported that he has planned, as a feature of the General Program, a scientific presentation of the sympathetic nervous system. The Board of Regents authorized him to invite some outstanding foreign guest on this subject, the name of Dr. Dale, of London, being prominently mentioned.

Dr. F. M. Pottenger reported that all local arrangements have been made for the San Francisco meeting, by Dr. Kerr and his several Committees, and that Dr. Kerr, as General Chairman, expects to have the complete program of clinics ready to submit in late August or early September. Dr. Pottenger also referred to a program of entertainment which the members of the College in Southern California, especially around Los Angeles, are arranging after the San Francisco Session.

Mr. E. R. Loveland, Executive Secretary, reported that he had made a trip to San Francisco and Los Angeles, in accordance with directions of the Regents, and that he, with the assistance of Doctors Pottenger and Kerr, had completed business arrangements for the 1932 Clinical Session. The Palace Hotel has been selected not only for hotel headquarters, but for general headquarters for registration, general scientific sessions, exhibits, etc. Railroad fares on the Certificate Plan of reduced rates will apply to all physicians and members of their families attending the Session. A special train will be operated from the East through to San Francisco, leaving there immediately after the Session taking members through the Yosemite Valley to Los Angeles and thence by way of the Grand Canyon back East. It is anticipated that the reduced fares will entitle members to optional return routes.

The Executive Secretary reported that the 1931-1932 Directory of the College will be ready for distribution about September 1

President White paid tribute to the late Dr Warthin by saying in part, "Dr Warthin's service to the College has been such an outstanding one, his Editorship of the Annals has been so acceptable and the Annals has been taking such a prominent place in Medical literature that his death leaves a serious loss"

A special Committee consisting of Dr S Marx White, Dr George Morris Piersol and Dr David P Barr was appointed with instructions to function immediately with respect to carrying on the Annals, to survey the situation with respect to a new Editor and an Editorial Board, to make recommendations concerning the manner in which the Journal should be managed, and to bring back recommendations to the next meeting of the Board of Regents

Upon motion by Dr Maurice C Pincoffs, seconded by Dr David P Barr, and regularly carried, it was

RESOLVED, the President shall appoint a Committee on Public Relations to which shall be referred all matters affecting the College or the medical profession in its relation to the public This Committee shall report its recommendations to the Board of Regents for approval or action The Committee shall consist of four members with the President a member ex officio, the terms of office shall be so arranged that one new member shall be appointed each year, with a maximum term of four years

President White appointed the following Committee on Public Relations

Charles G Jennings, Chairman	4 years
Walter L Bierring	3 years
James Alex Miller	2 years
W Blair Stewart	1 year
S Marx White (President, ex officio)	
Adjournment	

DOCTOR ALFRED STENGEL

Dr Alfred Stengel (Master), Philadelphia, was appointed Vice President of the University of Pennsylvania, in charge of medical affairs, at the annual Commencement of that institution on June 17 Through Dr

Stengel's appointment, the University of Pennsylvania plans a coordination of all the existing schools and departments included in the medical, dental, hygiene, veterinary and physical educational work This will embrace the University of Pennsylvania School of Medicine, the Graduate School of Medicine, the Phipps Institute, the Wistar Institute, the University Hospital, Graduate Hospital, the Orthopedic Hospital and the Institute of Mental Health of the Pennsylvania Hospital

Dr Stengel is a graduate of the University of Pennsylvania School of Medicine, and has been connected with the medical faculty since 1893 He is at present Professor of Medicine, both in the School of Medicine and in the Graduate School of Medicine; he is a term trustee of the University of Pennsylvania, a member of the Trustees' Executive Board, a member of the Trustees' Board of Medical Affairs, and a member of the Managing Committee of the University of Pennsylvania Fund On the occasion of the 165th anniversary of the founding of the School of Medicine last year, Dr Stengel was awarded the honorary degree of Doctor of Laws He also holds the degree of Doctor of Laws from Lafayette College and the degree of Doctor of Science from the University of Pittsburgh

Dr Stengel was President of the American College of Physicians for two successive years, 1925-1926 and 1926-1927 He has rendered distinguished service to the College for many years, and was made a Master during the Boston Clinical Session in 1929

Announcement is made of the prospective organization of an Association among those seeking post-graduate courses in Medicine given in English in Berlin With this Association the present Dozentenverein of the University of Berlin will cooperate The general plan contemplates an organization similar to the well-known American Medical Association of Vienna Inquiries and applications may be addressed to the organizing secretary, Miss Anny Engel, whose present address is Vienna I, Bösendorferstrasse 6, Austria

COLLEGE LIBRARY OF PUBLICATIONS BY MEMBERS

Members of the College are urged to contribute copies of books of which they are authors or co-authors to the College Library. The following Fellows recently contributed the books named

Dr James S McLester (Fellow), Birmingham, Ala

"Nutrition and Diet in Health and Disease"

Dr. Bernard L Wyatt (Fellow), Tucson, Ariz

"Chronic Arthritis and Rheumatoid Affections"

Dr Edwin Henes, Jr (Fellow), Milwaukee, Wisc

"Minneapolis Proceedings of the Interstate Postgraduate Medical Association of North America"

In addition to the above gifts, acknowledgment is made of the receipt of a considerable number of reprints, from the following members.

Dr Jacob M Cahan (Fellow), Philadelphia, Pa—8 reprints,

Dr Gustave P Grabfield (Fellow), Boston, Mass—20 reprints,

Dr. A Morris Ginsberg (Fellow), Kansas City, Mo—1 reprint,

Dr Earle E Mack (Associate), Syracuse, N Y—1 reprint;

Dr. Philip B. Matz (Fellow), Washington, D C—2 reprints,

Dr. Carl V. Vischer (Fellow), Philadelphia, Pa—1 reprint;

Dr Joseph R Darnall (Fellow), Riverdale, Md—1 reprint;

Dr. George R. Minot (Fellow), Boston, Mass—13 reprints,

Dr. Aaron E Parsonnet (Fellow), Newark, N J, with Dr. Albert S. Hyman (Fellow), New York, N. Y—4 reprints;

Dr. William D Reid (Fellow), Boston, Mass—2 reprints;

Dr John M. Swann (Fellow), Rochester, N. Y—19 reprints;

Dr. C F Tenney (Fellow), New York, N. Y—3 reprints,

Dr Robert A C Wollenberg (Fellow), Detroit, Mich—1 reprint,

Dr. Bernard L Wyatt (Fellow), Tucson, Ariz—5 reprints

At the 64th annual meeting of the West Virginia State Medical Association, held at Clarksburg, May 19-21, contributions were made to the program by the following members of the College

Dr Sydney R. Miller (Fellow), Baltimore, Md—"Arthritis",

Dr W. H Mayer (Fellow), Pittsburgh, Pa—"The Nervous Patient and the General Practitioner";

Dr. John N Simpson (Fellow), Morgantown, W Va—"What the Medical Department of West Virginia University Has Accomplished Since its Inception",

Dr. Howard T Phillips (Fellow), Wheeling, W. Va—"Ringworm Infection of the Hands, Feet and Groins";

Dr Albert H. Hoge (Fellow), Bluefield, W. Va—"Hypothyroidism as a Cause of Chronic Infection",

Dr Ray C. Blankinship (Fellow), Madison, Wis—"Medical Aspects of Jaundice",

Dr. G H Barksdale (Associate), Charleston, W Va—"Oration on Medicine"

Dr. James B Herrick (Fellow), Chicago, delivered the Abner Welborn Calhoun Lecture on "Common Errors in the Treatment of Heart Disease" at the eighty-second annual session of the Medical Association of Georgia, held at Atlanta, May 12-15.

Dr. William Gerry Morgan (Fellow), Washington, D. C., President of the American Medical Association, also delivered an address

Col Charles R. Reynolds (Fellow), Carlisle Barracks, Pa, delivered the chief address on field training for medical officers at the annual conference of the medical subchapter of the Cook County (Ill) Chapter of the Reserve Officers Association, U. S. Army, at Chicago, on May 18

Dr. Benjamin Goldberg (Fellow), Chicago, has resigned as Medical Director of

the Chicago Municipal Tuberculosis Sanitarium

Dr Thomas Addis (Fellow), Professor of Medicine, Stanford University Medical School, San Francisco, delivered the fourth course of lectures under the William Sydney Thayer and Susan Read Thayer Lectureship in Clinical Medicine in the School of Hygiene and Public Health of the Johns Hopkins University School of Medicine, Baltimore, May 11 and 12. The title of his first lecture was "The Natural History of Glomerular Nephritis," and the second lecture, "Questions in Connection with the Prognosis, Treatment and Etiology of Glomerular Nephritis"

Dr James B Bullitt (Fellow), Chapel Hill, N C, delivered the annual oration on "State Medicine" before the sixty-fourth annual meeting of the Mississippi State Medical Association, held at Jackson, May 12-14

Dr Edward O Otis (Fellow), Exeter, N H, was the recipient of a gold medal for fifty years of membership in the New Hampshire State Medical Association at its annual meeting in Manchester, May 19-20. Dr Otis has long been an enthusiastic, influential and active worker in New England medical organizations, as well as in many national societies

Dr William Gerry Morgan (Fellow), Washington, D C, delivered two addresses during the New Hampshire Medical Society's annual meeting

Dr Paul D White (Fellow), Boston, and Dr George Blumer (Fellow), New Haven, were also guest speakers, their titles being "Significance and Treatment of Cardiac Symptoms and Signs" and "Coronary Occlusion and Angina Pectoris," respectively

The following Fellows contributed articles indicated in the June Issue of the American Journal of the Medical Sciences

Dr James H Means (Fellow), Boston, Mass (with Lerman)—"Iodine in Exophthalmic Goiter. A Comparison of the

Effect of Ethyl Iodide and Potassium Iodide with that of Lugol's Solution", Dr Louis P Hamburger (Fellow), Baltimore, Md—"Head Murmurs"

Dr I S Trostler (Fellow), Chicago, recently addressed the LaPorte County (Ind) Medical Society

Dr Trostler also presented a paper on "Roentgenotherapy in Benign Diseases" before the Illinois State Medical Society at East St Louis, Ill, on May 6, a paper entitled "A Few Interesting X-Ray Findings with Clinical Summaries" before the North Side Branch of the Chicago Medical Society, May 14, and a paper on "Reports on Roentgen Findings" before the Section on Radiology of the American Medical Association at Philadelphia on June 11

Dr Maximilian J Hubeny (Fellow), Chicago, recently officiated as Toastmaster at the banquet of the Wisconsin State Medical Society, Section on Radiology, at Milwaukee

The Radiological Society of North America will hold its 17th annual meeting at the New Jefferson Hotel, St Louis, Mo, November 30 to December 5, 1931

Dr Edwin C Ernst (Fellow), St. Louis, acted as Secretary of the American Delegation to the Third International Congress on Radiology, which was held in Paris during July

Dr Benjamin H Orndoff (Fellow), Chicago, presented a paper on "The Treatment of Breast Carcinoma" before the Section on Radiology of the Illinois State Medical Society's meeting on May 7

Dr Harold Swanberg (Fellow), Quincy, Ill, is Secretary of the Secretaries' Conference of the Illinois State Medical Society

Dr Louise Tayler-Jones (Fellow), Washington, D C, is Vice President of the Medical Women's International Association, which represents twenty-two countries. Dr

Taylor-Jones will attend the next meeting of this organization in Vienna during September

Dr Elizabeth Bass (Fellow), New Orleans, La, Dr Martha Tracy (Fellow), Philadelphia, and Dr. Louise Taylor-Jones (Fellow), Washington, D C, each contributed articles to the March issue of the Medical Review of Reviews

Dr Arthur Bloomfield (Fellow) and Dr Walter W Boardman (Fellow), both of San Francisco, Calif, presented a very interesting clinic on gastro-intestinal diseases before the California Medical Association's meeting in May

Dr. Clyde Brooks (Fellow) has resigned as Professor of Physiology and Chairman of Research at the University of Alabama to accept an appointment as Head of Physiology and Pharmacology of the new medical center which is being developed on the campus of Charity Hospital, New Orleans, under the auspices of the Louisiana State University

The new medical school, at the beginning, will have a first year and a third year class of medical students opening this autumn. Dr. Aristides Agramonte, of Havana, has accepted the appointment as Head of the Department of Tropical Diseases

Dr Grafton Tyler Brown (Fellow) and Dr Oscar B Hunter (Fellow), Washington, D C, were contributors to the Allergy Exhibit at the Philadelphia meeting of the American Medical Association. Their contribution consisted of an exhibit of fungi (molds and yeasts) in relation to allergic conditions

Dr Brown presented a paper on 'Maximum Dosage in Pollen Therapy' at the Ninth Annual Meeting of the Association for the Study of Allergy in Philadelphia on June 10

Dr. Roy H. Allen (Fellow), Philadelphia, is the Campbell Lecturer of the Eastern College Medical Society at Union College, Schenectady, N. Y.

Dr. Allen also presented a paper on

of graduate instruction given by the Medical School of the University of Michigan at Ann Arbor, lecturing the entire day of May 20

Dr Harold S Davidson (Fellow), Atlantic City, N J, made the address of welcome to the American Therapeutic Society's meeting in Atlantic City, June 5-6

Dr Clement R Jones (Fellow), Pittsburgh, Pa, is President, Dr Grafton Tyler Brown (Fellow), Washington, is Secretary, and Dr Truman G Schnabel (Fellow), Philadelphia, is Treasurer

Dr Joseph C Doane (Fellow), Associate Professor of Medicine, Temple University of Philadelphia, and Associate Professor of Medicine, Graduate School of Medicine, University of Pennsylvania, recently spoke before a joint meeting of the Fifth Councillor District of the State Medical Society of New Jersey and the Atlantic County Medical Society at Atlantic City, N J, on the subject "What the Public Thinks of the Present Day Practice of Medicine", Dr Doane addressed the Philadelphia College of Physicians recently on "Some Observations on the Study of the Results of One Hundred and Seventy-five Post Mortem Examinations", and again the Atlantic County Medical Society, May 8, on "Diseases of the Endarteries"

Dr Benjamin Hobson Frayser (Fellow) has recently been transferred from the U S Veterans' Hospital at Fort Harrison, Mont to the U S Veterans' Hospital at Lexington, Ky

Dr Harry Gauss (Fellow), Denver, Colo, addressed the Medical Society of the City and County of Denver, May 18, on 'The Etiology and Management of Chronic Diarrhea'

The C V Mosby Company, of St. Louis, has recently published in book form "Clinical Diets"

An interesting paper on the preparation of the Blue Book Medical Society of the American Medical Association was presented at the St. Louis meeting of May 10, 1934

Fellows, not previously mentioned, are included

Dr Andrew C Ivy (Fellow), Chicago—"Facts Concerned in Gall Bladder Evacuation",

Dr Nathan S Davis, III (Fellow), Chicago, Secretary of the Chicago Medical Society—"Public Relations of the County Medical Society"

Dr William H Kraemer (Fellow), Wilmington, Del, addressed the Faculty Club of the University of Delaware, at one of its recent monthly meetings, on "Some of the Leading Problems in Medical Research of the Present Day"

Dr Kraemer also addressed the Commission on Cancer of the State of Pennsylvania at the Moses Taylor Hospital on the subject, "The Medical Treatment of Cancer"

Dr Kraemer is Director of the Tumor Clinic of the Jefferson Hospital of Philadelphia. The Tumor Clinic was founded through the creation of the "Elizabeth Storck Kraemer Memorial Fund," through the contributions by Mr Pierre S de Pont of \$25,000 for furniture and apparatus, \$10,000 additional toward fitting up the Department, and \$10,000 annually for five years toward the expenses of the practical work of the Clinic. Mr Lamot du Pont also contributed \$15,000 toward the support of the work of the Clinic. "The object of this clinic is research for the advancement of the knowledge of cancer along lines of surgery, x-ray, radium and chemical compounds, such as lead, which study has been pursued actively at Jefferson Hospital during the last two years"

Dr John I Marker (Fellow), Davenport, Iowa, addressed the St Louis Medical Society, Duluth, Minn, June 11, on "The County Contract for Care of the Indigent"

At the meeting of the National Tuberculosis Association at Syracuse, N Y, during May, Dr P P McCain (Fellow), Sanatorium, N C, was re-elected for a two-year term on the Board of Directors, and Dr L B McBrayer (Fellow), Southern Pines, N C, was re-elected to membership on the Committee of Health Education

The following Fellows of the College are members of the Board of Directors of the North Carolina Tuberculosis Association

Dr Paul Ringer, Asheville,
Dr P P McCain, Sanatorium,
Dr M L Stevens, Asheville,
Dr S D Craig, Winston-Salem,
Dr W B Kinlaw, Rocky Mount,
Dr William H Smith, Goldsboro,
Dr L B McBrayer, Southern Pines

Dr Robert M Moore (Fellow), Indianapolis, recently addressed the Tenth District Medical Society at East Chicago, and the Hancock County Medical Society at Fortville, his subjects being "The Heart in Surgery" and the "Management of Certain Types of Cardiac Cases," respectively

Dr Samuel E Munson (Fellow), Springfield, Ill, was recently re-elected Councilor of the Fifth District of the Illinois State Medical Society for three years. Dr Munson has held this office since 1925

Dr Oliver T Osborne (Fellow), New Haven, Conn, has been nominated to the "Hall for Famous Men" of The Heckscher Institute for Child Health, New York City

Dr Curran Pope (Associate), Louisville, Ky, delivered a radiophone address on May 5 over station WLAP, at Louisville, under the auspices of the Woman's Auxiliary of the Jefferson County Medical Society, his subject being "The Conservation of Nervous Energy"

Dr Pope was a guest of the West Virginia State Medical Association at their annual meeting in Clarksburg, W Va, May 19-21. Dr Pope discussed a number of papers on the program, and also delivered an address at the luncheon of the Rotary Club

At the annual meeting of the Board of Trustees of Syracuse University in May, the following promotions were made in the faculty of the College of Medicine: Edward C Reifenshein (Fellow) to Professor of Medicine, Maynard E Holmes (Fellow) to Assistant Professor of Clinical Medicine

Dr David Riesman (Fellow), Philadelphia, was elected President of the American Association of the History of Medicine at its recent meeting in Atlantic City

Dr Raymond W Swinney (Fellow) has removed from Kansas City, Mo, to Long Beach, Calif

Dr Carl V Vischer (Fellow), Philadelphia is co-author with Dr Thomas J Vischer (Associate), Philadelphia, of an article in the May Hahnemannian Monthly, "The VonPirquet Test, its Value as an Aid in the Diagnosis of Tuberculous Infection"

Dr Conrad Wesselhoeft (Fellow), Boston, was appointed Associate in Communicable Diseases, Department of Pediatrics, Harvard University Medical School, on June 3

"Forty Years as a Clinical Pathologist" was the title of a paper that appeared in the May, 1931, Issue of the Journal of Laboratory and Clinical Medicine under the authorship of Dr Aldred Scott Warthin (Master), Ann Arbor, Mich, now deceased

Dr Carl H Greene (Fellow) and Dr Albert M Snell (Fellow) (with Walters), Rochester, Minn, contributed an article to the same journal entitled "Functional Tests in the Surgical Diagnosis and Treatment of Diseases of the Liver and Bile Ducts"

Dr Henry J John (Fellow), Cleveland, also contributed an article on "Surgery in the Presence of Diabetes"

In the June issue of Radiology, the following Fellows contributed articles

Dr Thomas A Groover, Washington, D C—"Radiology as a Career",

Dr. L J Carter, Brandon, Man, Canada—"The X-Ray Treatment of Essential Heartburn",

Dr. L S Trostler, Chicago, Ill—"An Obscure Bone Case"

Annals of Specialties is listed in the preliminary program for the graduate course of clinical conferences for general practitioners held in St Louis June 15 to 20

appeared the names of the following Fellows

Dr W W Duke, Kansas City, Mo

Dr William Engelbach, New York, N. Y

Dr L G Rowntree, Rochester, Minn

Dr B B Vincent Lyon (Fellow), Philadelphia, addressed the Medical Society of New Jersey at Asbury Park, June 3 to 5, on "Value of Duodenal Tube Drainage of the Biliary System and Treatment of Various Diseases and Disorders of the Liver"

Dr Elias H Bartley (Fellow), Brooklyn, recently retired as President of the Medical Board of the Kingston Avenue Hospital for Contagious Diseases Dr Bartley was a member of the Board for thirty years, and President for fifteen years

Dr Otis S Warr (Fellow), Memphis, addressed the West Tennessee Medical and Surgical Association, May 20 to 22, on "Undulant Fever"

At the annual meeting of the Medical Society of the District of Columbia, May 6-7, the following Fellows of the College took part

Dr William Gerry Morgan, Washington—"Some of the Medicinal Effects of Alcohol",

Dr Walter Freeman, Washington—"Malaria Treatment of Neurosyphilis",

Dr Alexander B Moore, Washington—"Gastro-intestinal Bleeding",

Dr J Russell Verbrycke, Jr, Washington—"Cardiospasm"

Dr Arthur C Christie (Fellow), Washington, was elected President, Mary O'Malley (Fellow), Washington, one of the Vice Presidents, and Dr Coursen B. Conklin (Fellow), Washington, was re-elected Secretary

Dr Cecil M Jack (Fellow), Decatur, Ill, addressed the Adams County Medical Society at Quincy, Ill May 11, on "Value of an Oblique Incision in a Tuberculous Sacrospinous Ligament"

Dr John H. H. (Fellow), Chicago, addressed the Chicago Medical Association

ciet, May 11, on "Premature Infants as a Present-Day Problem"

Dr J A Barga (Fellow), Rochester, Minn, addressed the Pennsylvania Radiological Society, May 13 to 14, at McKeesport on "Clinical and Radiological Aspects of Chronic Ulcerative Colitis"

Dr Marr Bisailon (Fellow), Portland, Ore, used as his subject "Differential Diagnosis of Malignancy of the Lung" in an address, May 4, before the King County (Washington) Medical Society

Dr Charles James Bloom (Fellow) addressed the St Tammany Parish Medical Society, June 12, 1931, on "Intestinal Disturbances in Infants and Children"

Dr Louis F Bishop (Fellow) and Dr Louis F Bishop, Jr (Fellow) addressed the American Therapeutic Society at Atlantic City, June 5, 1931, on "A Study of Cardiovascular Syphilis in Private Practice"

Dr G L Pinney (Fellow), Hastings, Nebraska, has been elected Delegate to the State Medical Meeting for the third successive year. At that meeting, May 14, he read a paper on "Cardiac Hypertrophy"

Dr Leon T LeWald (Fellow), Professor of Roentgenology, New York University and Bellevue Hospital Medical College, read a paper entitled "Gastric Lesions, Roentgen Diagnosis and Differential Diagnosis from Gastric Ulcer and Carcinoma" before the Connecticut State Medical Society at Bridgeport, Conn, on May 20th, 1931

OBITUARY

DOCTOR FRANCIS XAVIER
DERCUM

Dr Francis Xavier Dercum, world-famous neurologist, died suddenly on April 23, 1931, a few minutes after the closing of the executive session of the American Philosophical Society. As president of the Society he had read his report and was about to open formally the 204th Annual Meeting when the end came. Seated in the chair of Benjamin Franklin, the founder, in the presence of an audience made up of distinguished scientists and surrounded by trophies of America's scientific progress over the last two centuries, an impressive and dignified setting completely symbolic of his distinguished career, he suddenly collapsed and passed away without regaining consciousness. "He died," remarked a fellow-scientist, "as a scientist would wish."

Born in Philadelphia, August 10, 1856, a son of Ernest Albert and Susanna Erhart Dercum, Dr Dercum attended the public schools of his native city and was graduated from the Central High School in 1873. At an early age Dr Dercum resolved to study medicine and in 1877 was graduated from the Medical Department of the University of Pennsylvania and in that year also won a Ph.D. from the same institution. While a student in the medical school, he devoted attention to scientific investigation and following his graduation this interest became a dominant attribute of Dr Dercum's life. He continued to study medicine for a number of years before he entered the service of the army.

He at once became a member of the Academy of Natural Sciences, Philadelphia, to which he made original contributions from time to time. In 1878 his ability as an anatomist was recognized by his appointment as an assistant demonstrator in the histologic laboratories under Dr Richardson, and very soon thereafter he was appointed demonstrator in the laboratory of physiology under Professor Harrison Allen. Here he demonstrated practical histology, fungi, algae, protozoa, and bacteria, "thus obtaining a solid foundation in what was then the new science of bacteriology."

In 1883, at the request of his friend and former teacher, Dr Horatio C. Wood, he directed his scientific studies to nervous diseases. Almost simultaneously he was appointed Chief of the Nervous Dispensary and Instructor of Nervous Diseases in the medical school of the University of Pennsylvania. While Dr Dercum was holding this position, Muiybridge began his studies of the movements of horses in the open lot behind the University Hospital. Muiybridge also photographed for Dr Dercum men exhibiting normal and pathological gait as well as persons in convulsions. In order to get pictures of persons in convulsions Dr Dercum would induce them artificially by suggestion under hypnosis. He and his disinterested brother made a report on artificial convulsions before the Philadelphia Neurological Society held at the University, the first of their kind. Dr Dercum's work in this field was of great value. He continued to study the nervous system and its diseases.

Nervous Diseases until 1892, when he was elected to the newly created chair of Nervous and Mental Diseases in Jefferson Medical College with the title of Clinical Professor and with a seat in the faculty. In 1925 he resigned this position and immediately became Professor Emeritus.

Dr Dercum was a member of many learned societies both at home and abroad, holding membership in the Philadelphia County Medical Society, American Medical Association, Association for Research in Nervous and Mental Diseases, Historical Society of Pennsylvania, Franklin Institute, Zoological Society, Alpha Kappa Kappa, Wistar Association, Royal Medical Society of Budapest (1909), Royal Society of Medicine at London, corresponding membership in the Psychiatric and Neurological Society of Vienna (1911), and honorary membership in The Society of Physicians of Vienna (1921). He was elected a Fellow of the American College of Physicians in 1923. Dr Dercum was neurologist to the Philadelphia General Hospital from 1887 until a few years ago, when he was made consulting neurologist. He was also consulting neurologist to the Jewish Hospital, Wernersville Sanatorium and State Hospital for Criminal Insane at Fairview. He was at one time pathologist to the State Hospital for the Insane at Norristown, Pennsylvania.

As a result of assiduous literary activity throughout his long career, Dr Dercum published upward of 200 papers. As early as 1878 his scientific papers began to appear in *The American Naturalist* and in the *Proceedings of the Academy of Natural Sciences*.

They included articles on "The Sensory Organs, Suggestions With a View to Generalization" and "The Morphology of the Semi-circular Canals and the Nerve Terminations in the Lateral Sensory Apparatus of Fishes." In 1895 Dr Dercum edited a textbook of nervous diseases by American authors. His later writings included "Rest, Suggestion and Other Therapeutic Measures in Nervous and Mental Diseases," 1904, a "Clinical Manual of Mental Diseases" 1914, "Hysteria and Accident Compensation," 1916, "Biology of the Internal Secretions," 1924, and "The Physiology of the Mind," 1925. The last named work met with world-wide appreciation among neurologists and biologists and showed the author's creative originality.

In 1892 he described the *Adiposis Dolorosa*, which bears his name and is referred to by French writers as "Maladie de Dercum." It may be said that though Dr Dercum helped to give clinical observation recognition as a scientific method, he was not exclusively a clinician, but was much engrossed in scientific investigations into the causes and nature of pathological and physiological phenomena. With his friend, the late Dr Mills, he was a pioneer in the study of nervous and mental diseases.

Dr Dercum joined with Charles K. Mills, Wharton Sinkler, and others in founding the Philadelphia Neurological Society, which he served as president for a time. On December 4, 1908, Dr Dercum was formally notified that he had been elected to the *Société de Neurologie de Paris*, composed of fifty leading nerve specialists.

of the world. The only other American who has been elected to that body is Dr Charles L. Dana of New York. During the World War Dr Dercum rendered important service as a member of the Medical Advisory Board and lecturer to the Army and Navy Medical Corps.

Dr Dercum became the president of the American Philosophical Society in 1927, here he found duties commensurate with his talent, and he manifested an insatiable love for the work. About one year ago he organized the American Philosophical Society's survey of mankind's intellectual progress. It may be truly said that he infused new life into this time-honored institution.

After paying tribute to Dr Dercum's ancestors, many of whom became lawyers, judges, scholars, scientists, and physicians, and two of whom were professors in the University of Wurzburg (an institution founded in 1582 and destined to be the place where Roentgen discovered the x-ray), J. Chalmers Da Costa* says, "He should have inherited predispositions to generosity, kindness, faithfulness, hospitality, patience, charity, courage and a love for science, music and romance. I believe that he has fulfilled the promises of his ancestry."

* Address delivered at a testimonial dinner in honor of Dr Dercum's seventieth birthday, December 11, 1923.

Dr Dercum was a man of unassuming person and demeanor. He was a popular man because of the natural sweetness of his nature and his propensity to embrace every opportunity for professional, public, and social diversion. His manner was refined and pleasing, and he was uniformly cordial to his troupes of friends, both in and out of the medical profession. Indeed, the health and well-being of many of the latter depended almost as much upon his kindly attention as upon his superior skill.

Although he constantly showed himself to be a man of profound intellect and breadth of view, we shall not understand his character nor his inner life unless we conceive him as one to whom the solution of abstruse problems, particularly in psychiatry and morbid physiology of mental and nervous diseases, was an insatiable desire.

His life had been complicated, for a period of several years prior to his passing, by physical infirmities, yet his spirit had ever risen above them, its fires being fed by God-given fuel, and his genius taking up, despite interruptions, the golden threads of tasks that death alone could terminate.

In 1892 Dr Dercum married Elizabeth De Haven Comly, a member of an old Philadelphia family. Mrs Dercum and two daughters, Mrs Samuel W. Mifflin and Miss Mary De Haven Dercum, survive.

Chronic Nonvalvular Cardiac Disease or Chronic Myocardial Insufficiency and Its Therapeutic Management*

By HENRY A. CHRISTIAN, M.D., F.A.C.P., *Boston, Mass*

IN an adult clinic more patients with cardiac disease without valve lesions are seen than those with valve lesions. Rheumatic fever is the largest cause of valvular disease, and this is chiefly a disease of childhood and early adult life. In children's clinics, apart from congenital heart disease, other than rheumatic valvular disease of the heart is unusual. The majority of patients with rheumatic heart disease die within a twenty year period of the inception of their heart lesion, and they have had the causative rheumatic fever in childhood. The result is a rapidly falling curve of incidence of rheumatic heart disease in hospital admissions in the years following the age of thirty.

Syphilis almost never causes any other form of heart disease than the aortic insufficiency associated with syphilitic aortitis or aneurysm. This, next to rheumatic fever, is the most frequent cause of valvular disease of the heart. The average time between causative infection with the spirochetes of syphilis and the evidences of aortic disease is between fifteen and

twenty years. Syphilitic infection is, as very aptly has been said, an incident in the bloom of youth. Certainly many syphilitic infections do begin before twenty-five. After the aortic lesion of syphilis has advanced to the stage of causing symptoms, life on the average is considerably under five years. These factors give us a rapidly falling curve of incidence of admissions to hospitals of patients with syphilitic aortic insufficiency following the forty year period of life.

After the forty year age level, hospitals have usually an increasing rather than a decreasing rate of admissions for cardiac disease, and these patients far more often than otherwise have neither the valve lesions of rheumatic heart disease nor the aortic lesions of syphilis.

As a result of examination, we know that, as a rule, these patients show the history and findings indicative of a failing circulation, symptoms and signs all too familiar for me to burden you with them, the heart with rare exceptions is enlarged, as usually can be detected by simple physical examination, but which in the obese and the emphysematous may require x-ray observation for its detection,

*Read at the Baltimore Meeting of the American College of Physicians, March 23, 1931

heart sounds and rhythm may be normal or abnormal; murmurs may be lacking, or some sort of a systolic murmur, ordinarily loudest in the apex region, may be heard

In the rheumatic group and in the syphilitic group of patients with heart disease disturbances of valve function play an important part in causing cardiac failure. In the rheumatic group it is notable that, when symptoms of cardiac failure develop, there are in most patients well marked signs of mitral stenosis with or without auricular fibrillation. In the syphilitic group it is very striking how little cardiac enlargement there is with aortitis and aneurysm until the aortic valve becomes incompetent, and as a rule, only after these developments do we have evidences of circulatory failure. It seems reasonable to speak of both these groups as forms of chronic valvular cardiac disease.

In contrast is the striking absence of evidence of valve lesion, when one examines the heart in a patient of this past-forty group who has had neither rheumatism nor syphilis. Whether the systolic apical murmur is prominent or not seems to play little part in the degree of observed evidences of heart failure. Why not then, in contrast, speak of these as chronic non-valvular cardiac disease?

In all three of these groups the clinician, if he has had opportunity to study carefully the patient prior to the last day or two of life, can describe with very considerable accuracy what the post-mortem examination will reveal. In few realms of medicine come so few surprising revelations by the pathologist. The predicted mitral

stenosis is revealed and other valve lesions, notably aortic ones, appear or not, as anticipated in the rheumatic group, the chief failure in clinical diagnosis concerns the tricuspid valve, which may show, though rarely, an unpredicted stenotic lesion. The predicted aortic lesion with incompetent aortic cusps is as expected in the syphilitic group. In the third group, the non-valvular group, is revealed, as predicted, the cardiac enlargement without other valve lesion than the enlarged orifice resulting from dilatation of the ventricles.

The clinician and the pathologist are in accord as to the rheumatic and syphilitic etiologies. If there has been clinical doubt, and there often is, as to the etiology in the third group, the pathologist very often fails to clear the doubt. Pathological study usually confirms the ideas derived by the clinician from his examinations of the patient during life; quite rarely does it add anything of importance to those ideas.

In the first and second groups (rheumatic and syphilitic) it seems reasonably certain that a disease process of known etiology has led to organic lesion of the heart valves, and that the consequent disturbance in cardiac function has played a significant part in the progressing disease with final death of the patient.

In the third group it seems equally certain that there has been no organic lesion of the heart valves and that such failure to function on the part of the valves, as has occurred, is probably secondary to the dilatation of ventricles resulting from dilatation of aortic cusps. It would not be surprising

third group of patients has not shown any etiological factor in evidence for all of the group, nor has it revealed any pathological lesion which consistently will explain the progressing cardiac failure that has led to the patient's death. In the gross the heart muscle looks strikingly well nourished, is normal in color and appears powerful as a muscle. In some, microscopic examination will show various types of degeneration of muscle fibres and nuclei, but these obviously are of recent origin and could have no great influence in determining a cardiac failure which has increased progressively for months or even years. As a rule the muscle fibres are larger than normal. At times coronary arteries will show considerable narrowing of the lumen indicative of a lessened nutritional circulation, but just as often this is not present (none or slight in 36.9 per cent, moderate in 28.3 per cent and marked in 35.1 per cent of 228 hearts studied at autopsy) *. In some there is a diffuse fibrosis, but this definitely is unusual, and incidentally such cases differ in no wise clinically from those without diffuse fibrosis. Focal fibrosis of microscopic proportions is found more frequently (fibrosis, none or slight in 68.6 per cent, moderate in 22.5 per cent and marked in 8.9 per cent of 228 hearts studied at autopsy). There may be pathological changes in the small, terminal branches of the coronary arteries (none or slight in 48.2 per cent, moderate in 34.1 per cent and marked in 17.7 per cent of 228

hearts studied at autopsy). Often both types of sclerosis of vessels are lacking. Cellular infiltration, usually focal, occurs but is neither extensive nor frequent. In a goodly proportion of these hearts histological study shows no lesion that in its extent of distribution conceivably could explain the obvious fact that the patient has died of cardiac failure (50 out of 223 hearts), while in many others the pathological lesion scarcely seems causative of observed symptoms. A minute knowledge of the architecture of the muscle of the heart throws no light on how small focal lesions could incommode seriously the function of the heart muscle. Conceivably focal lesions might inaugurate damaging arrhythmias, but if these develop, they are relatively late in their appearance, and often these patients died without ever showing any arrhythmia.

From the clinical study of these patients it is obvious that syphilis plays no important etiological rôle, very rarely it may be a cause. Rheumatic fever certainly does not cause the disturbance. Focal infection may, at times, be a cause, but there is no satisfactory proof of this. No evidence incriminates any other infection. Definite endocrinopathies, except occasionally thyroid disturbances, are of no causative significance. In one-half to two-thirds of these patients hypertension with or without arteriosclerosis and with or without nephritis is or has been present. When it exists, it certainly would seem to be at least a contributory, if not the chief cause, and yet there are many unanswerable riddles, as we watch the progress of cardiac disability in the patient with

*These statistical studies were made at the Peter Bent Brigham Hospital by Greene FitzHugh, *New England Journal of Medicine*, 1930, ccxi, 201.

hypertension Cases in every way identical with those of later life occasionally are observed at birth and in early childhood, so the aging process does not serve as a satisfactory cause

It is very striking how definite and convincing is our knowledge of what is going on, and why, in the rheumatic and syphilitic group, in contrast to its uncertainties and unconvincingness in regard to this third, or non-valvular, group

From what has been said, it is clear that, with our ignorance as to etiology in this group of non-valvular cardiac patients, methods of prevention will not be helpful in our management. The only cases with any very constant accompaniment of anything of possible etiologic significance is the hypertensive group. Assuming that in these hypertension is the cause, which may not be the case, how little does that help so long as we remain in the present state of uncertainty as to methods of controlling hypertension. We can lessen added stresses and strains but do little more than this. In those definitely of thyroid origin, the plan of treatment is directed to restoration of thyroid function to a normal level and that is not difficult. Definite foci of infection should be eliminated whenever possible; even if not etiologically important in the cardiac lesion, it is helpful to the patients' general condition to eradicate them. Indiscriminate removal of tonsils and teeth, drainage of sinuses, etc., because they might be foci of infection, is reprehensible though a frequent practice, as judged from what has happened in cases where I saw patients. The removal of tonsils and teeth are not

avoided; many vagaries of diet are advised by food faddists which run from nothing but grapes to almost nothing but sun-kist oranges through purely vegetarian, largely meat, fat-poor, salt-poor, vitamin-rich, sugar-poor, carbohydrate-rich, and only milk and largely nut diets with the expectancy that soon some one will exploit a blubber diet which seems consistent only with life in the arctic or antarctic region, all of which dietary regimes seem to succeed in ratio to the psychological influence of the advisor and the psychopathic complex of the advisee. Excesses of weight should be reduced very gradually by food restrictions alone; one pound per week is my advised rate for the ambulatory patient.

A readjustment of mental and physical activities in accordance with circulatory disability helps much with these patients, whether they show little or much evidence of circulatory malfunction. When symptoms develop, rest with digitalis should be instituted and then a gradual return to a modified amount of activity. Increasingly I advise these patients to take continuously a daily dosage of digitalis, for most patients the equivalent in digitalis value of 0.1 gram of powdered leaves, the preparation of digitalis used seems to me to be immaterial provided it is an efficient preparation. Some patients will not tolerate 0.1 gram per day; they should have less in accord with their determined tolerance. I believe patients, who have had only the slightest evidence of cardiac inefficiency, probably from such continued digitalis ingestion. The reason for this is that the

the belief that digitalis dosage might well be commenced when cardiac enlargement is detected, even though no symptoms of cardiac insufficiency have yet appeared. The belief that digitalis is useful only in the presence of auricular fibrillation seems still to persist, though there is much very striking clinical evidence against it, especially strong for this particular group of patients.

Terminology for this group of patients is confused. Chronic non-valvular cardiac disease seems to me a good

term. Chronic myocardial insufficiency is not unsatisfactory. Chronic myocarditis, too, would be satisfactory, if one will admit that it does not connote inflammation of the myocardium, but long usage renders that difficult. Any of these terms can be modified by adding an adjective descriptive of the cause, when known, such as hypertensive, hyperthyroid, etc. On the basis of present knowledge I prefer chronic non-valvular cardiac disease, if one speaks of the other groups as cases of chronic valvular cardiac disease.

Circulatory Adjustments in Heart Disease: A Concept of Circulatory Failure*†

By SOMA WEISS, M D , F A C P , *Boston, Mass*

INTENSIVE clinical and experimental studies of the heart and circulation during the past quarter century have shed considerable light on problems of the cardiovascular system. The accumulated facts, however, are of less aid in understanding the clinical picture of cardiac and circulatory diseases than one would expect. Discoveries with the galvanometer have revealed in detail the mechanism of various disturbances in the conduction of nerve impulses and in the excitability of the myocardium. Correlations between the clinical behavior of the patient and the electrocardiographic findings have made the clinical diagnosis of cardiac pathology more accurate than before, but, on the other hand, have disclosed little concerning the efficiency of the heart. The electrocardiogram is not a direct measure of the state of the circulation. A patient with auricular fibrillation, diagnosed as "pulsus irregularis perpetuus" during the Spanish-American War,

is still at hard daily physical work. Another patient, showing a similar electrocardiogram, is dying with congestive failure of the circulation. Recently we observed a patient who maintained a fairly efficient circulation with ventricular tachycardia for thirty-five days and then reverted to normal sinus rhythm.

A majority of the symptoms and signs of the patient with cardiovascular disease depend rather on the state of the circulation than on the heart. Knowledge of the conditions underlying the clinical picture of circulatory failure is still exceedingly meager. We have no satisfactory explanation of why one patient develops an early hydrothorax, while another dies of massive peripheral edema with no trace of fluid in the pleural cavity. The interpretations of the correlation of the clinical manifestations of heart disease are but empirical and often confusing.

It is not surprising that progress in this branch of medicine has lagged behind, for the factors which determine the clinical picture of circulatory failure are numerous and variable. If one is present in the differential correlation between the clinical picture and the state of the circulation, the picture is still more confusing.

unfavorable changes Furthermore, not only are there various changes and adjustments present in different types of heart disease; but in different stages of the same type of heart disease, new factors, or different combinations of factors, may be responsible for the same clinical manifestation To understand circulatory failure, a study of the patient with a correlation of the combined chemical, physiological and morphological factors, instead of a separate analysis of single aspects, is especially important Chemistry, physiology and anatomy are dependent on each other; they may be separated successfully in theory but are combined with equal importance in practice

From the available evidence it is thus difficult to construct as yet an accurate and detailed picture of the sequence of events in the progress of circulatory failure The difficulty is great not only because numerous gaps exist at the most crucial points of the problem, but also because results of the investigations are often contradictory even concerning the most diligently studied aspects of the circulation A concept, therefore, which attempts to correlate the clinical picture with the functional and structural changes of circulatory failure can be at its best, but incomplete Nevertheless, it is desirable from time to time to assemble the scattered blocks of knowledge and then inspect them from a distance in the hope that they may assume the outlines of a real structure, even though broken by spaces Such a concept, despite its incompleteness, helps in the estimation of the clinical condition of the patient ^{medical} and in the

proper application of therapeutic measures

In the course of this limited discussion it is impossible to enter into an intricate interpretation of the individual symptoms and signs of circulatory failure The following presentation will therefore be limited to those alterations of circulatory function which bear closely on the clinical manifestations of circulatory failure Factors referable to the heart will not be discussed Correlations of the circulatory functions are presented partly from clinical observations and investigations conducted in the Boston City Hospital during the past five years, and partly from the results obtained by other investigators Occasionally, when reliable observations on man are not available, analogous experimental observations on animals are used It is hoped that clinical studies in progress will yield more direct proof on these points Controversial discussions will be omitted

I. HEART DISEASE AND CIRCULATORY FAILURE

Whenever the circulation fails to accomplish its task of efficiently supplying the tissues with nourishment and promptly eliminating the waste products of cell metabolism during the normal activities of life, we speak of circulatory failure Normal circulatory efficiency, like so many other biological functions, is a broad average since considerable variation exists among healthy individuals Heart disease may coexist with a circulation normal in every respect for years. Often, however, long before actual impairment of the efficiency of the body

occurs, alterations and adjustments take place in various parts of the circulation. Thus, for example, a patient may perform normal amounts of daily work, but accomplish this with a higher expenditure of cardiac energy, an increased ventilation of the lungs, a higher arterial blood pressure, and an increased utilization of oxygen and exchange of other substances between the capillary blood and tissue cells. These adjustments make it possible for the patient to perform vital functions which otherwise could not be carried on.

In the presence of heart disease the nature of the readjustment of the circulation depends to a certain degree quantitatively and qualitatively on the localization and etiology of the cardiac lesions. However, failure of the circulation may be independent of heart disease. For this reason, it is erroneous to speak of heart disease and circulatory failure interchangeably. Circulatory failure often results from primary derangement of the vasomotor system. Such is the case in the progressive vasomotor collapse (shock) which follows surgical operations and other types of trauma, in certain diseases of the nervous system, infectious diseases and toxemias. The clinical picture of vasomotor collapse is quite distinct from that of congestive heart disease. The patient is pale; dyspnea may be present but without orthopnea; the veins are collapsed instead of being dilated; the circulating blood volume is early reduced, due to stagnation of blood in the peripheral minute vessels. Correspondingly, there is a decrease in the minute and stroke volume output of the heart:

and as a result of this, the venous and arterial blood pressures fall below normal although the mean velocity of blood flow may be unaltered^{1,2}. There is a depletion of the blood content of the large vessels and chambers of the heart, and an overfilling of the peripheral minute vessels due to purposeless relaxation of the arterioles and perhaps other minute vessels. The heart expels with ease whatever blood reaches its chambers.

Vasomotor collapse does not always exist in this pure form, as the chemical factors which cause the collapse may also depress the heart function. This may be the case in lobar pneumonia. In such instances the clinical picture and the type of circulatory failure depend on a combination of vasomotor collapse and heart failure.

Certain investigations have suggested that primary changes in the peripheral circulation are also responsible for the failure of the circulation in heart disease. Thus it has been claimed that primary disturbances in the lactic acid metabolism cause important changes in the peripheral vascular system and precipitate the sequence of events that results in circulatory failure. A recent investigation in the Boston City Hospital fails to support this claim. No primary disturbances of the lactic acid formation before the appearance of an inadequate blood flow could be discovered. All the evidence obtained by us thus far supports the logical concept suggested by clinical manifestations and post mortem finding, that local disturbances of the heart are primarily responsible for the circulatory changes.

The clinical picture of circulatory failure varies, depending on the etiology of the heart disease and the seat of the lesions. Because the cardiac lesions are rarely in pure form and the size and rate of their development are usually unknown factors, the clinical picture of failure varies considerably even in a group of patients with similar morbid changes in the heart, so far as can be judged from clinical observations.

In this presentation, for the sake of simplicity, the circulatory adaptations will be correlated, as a rule, with the normal basal metabolism at rest. In reality the circulatory efficiency can be considered as an index between efficient capillary blood supply and tissue metabolism. This index may be disturbed both by abnormal changes of the circulation or by increase in metabolism. For obvious reasons, in the presence of markedly increased metabolism a relatively slight circulatory failure leads to severe clinical disturbances. Clinical symptoms and signs are often the expressions of an altered balance rather than absolute deviations from normal. In addition to changes in the heart, numerous extracardiac factors may influence the circulation and thus the clinical picture. Of these factors, fever of bacterial or non-bacterial origin; altered hemoglobin and protein content of the blood, pulmonary pathology, especially emphysema and bronchitis; and internal secretory disturbances are most important. The way in which these factors influence, at times fundamentally, the circulation cannot be discussed here.

II. EARLY STAGES OF CIRCULATORY FAILURE

"Congestive heart failure" with dyspnea and orthopnea at rest, râles over the base of the lungs, hydrothorax, enlarged liver, ascites, and dependent edema is usually the end picture of chronic disease of years' duration. For a long period before this stage of circulatory failure is reached the patient is comfortable at rest and develops circulatory embarrassment only after exertion. At this stage, the patient with heart disease differs apparently from normal subjects only in the degree of muscular activity that brings on dyspnea and weakness. This early stage is the longest period in the natural course of heart disease, and it is in this stage that intelligent preventive measures will ameliorate and prolong the life of the patient. Unfortunately, this period of circulatory failure is most incompletely understood.

At the onset of circulatory failure the symptoms and signs are referable almost entirely to local disturbances in cardiac function. The main symptom referable to the circulation is dyspnea; and it is the mechanism underlying this dyspnea that is the center of the problem. If one examines the state of the peripheral circulation at this stage one finds that the arterial, capillary and venous blood pressures are unaltered. The cardiac output per minute may be normal or slightly reduced^{4,5}. The velocity of blood flow as observed in the capillaries of the finger nail bed⁶ as well as in the large veins of the forearm⁷ is frequently normal. Hence the velocity in the

arteries must also be unaltered. Similarly, the arterio-venous oxygen differences of the arms and legs and the lactic acid content of the arterial and venous blood are normal⁸. In other words, all the studies with available methods indicate that the blood supply of the organs is adequate and normal at rest. Even more significant is the fact that if a patient performs a walking exercise sufficient to induce dyspnea, and the arterio-venous oxygen differences are studied by repeated punctures of the femoral and cubital veins, not only the volume difference of oxygen but the rate of the return of the oxygen difference to normal is the same in cardiac patients with dyspnea as in the normal subject who experiences no difficulty in performing the same exercise⁹. It is also significant that the curve of the lactic acid content of the blood in the femoral vein after exercise shows the same rise and return to normal as that of normal individuals. There is no difference in the lactic acid overflow into the blood from exercised muscle in the dyspneic cardiac patient and in the normal subject who experiences no dyspnea³. These recent observations indicate that in the early stages of circulatory failure, when the patient becomes dyspneic after mild exercise, the peripheral supply of blood to the tissues may still be adequate and the lactic acid formation in the exercising muscle not disturbed.

What, then, are the factors which show deviation from normal at this stage? One does find early a reduction of the vital capacity of the lungs^{10,11}. Simultaneously, or somewhat later, the blood flow through the lungs is re-

tarded. If the total lung volume, as well as the interrelation between various portions of the respiratory space are measured, one finds that the total lung volume is normal or may even be increased^{10,11}. The residual air, instead of being decreased as one would expect from the diminished vital capacity, may be increased both relatively and absolutely, often at the expense of the reserve air, which decreases. A disproportion therefore develops between the residual air and the reserve air¹¹. Unfortunately, no observations on the pressure relations in the pulmonary circuit in man are available.

Is it possible to correlate these physiological observations with the structural changes and the behavior of the patient? It seems significant that all the abnormal findings observed in the early stages of circulatory failure bear on the pulmonary circulation and on the structural and physiological alterations of the respiratory surface while, on the other hand, the larger circulation shows no morbid changes. This obviously justifies two conclusions of great significance. (a) *that in early stages of circulatory failure changes occur in the pulmonary circulation;* and (b) *that changes in the pulmonary circulation may be independent of the larger circulation*.

In rheumatic, syphilitic, hypertensive and arteriosclerotic heart disease it is in the pulmonary venous system that the first effect of the heart disease manifests itself*. The back pressure

*Triumphal disease without other vascular disease in rheumatic heart disease, and coronary sclerosis may have the blood supply of the right ventricle alone as its source.

effect in cases of mitral disease and in cases of failure of the left ventricle is obvious. Its occurrence was claimed, long before the application of physiological concepts to clinical medicine, by morphologists of the 17th century. But the significance of this back pressure effect has not been examined in detail. If the left ventricle is not normally efficient and a certain amount of blood accumulates in the pulmonary vein, one or a combination of two possibilities may occur. (a) there being no essential alteration in the cross-sectional area of the vascular portion which offers the resistance to the right ventricle, *the increase in the pulmonary venous pressure will result in a proportional increase in the pulmonary capillary pressure, and later, in the pulmonary arterial pressure,* (b) *a considerable increase in the cross section and volume of the vascular bed of the pulmonary circuit may result without necessitating much alteration in pulmonary arterial pressure.* Teleological and experimental evidence strongly supports the presence of the second factor in early stages of circulatory failure.

It is now established that reserve capillaries exist in almost all the organs so far investigated. It would be most unusual if the lungs, the specific function of which depends entirely on capillary activity, did not possess such reserve capillaries. Their existence in the lungs has been suspected ever since the work of Cohnheim and Litten¹² in 1876. In rabbits, reserve capillaries which open during physiological activity were graphically demonstrated by Toyama¹³ in 1925. In cats, the opening of new capillaries was ob-

served by Wearn, Barr and German¹⁴. Hall¹⁵ denies the appearance of new capillaries in the lungs with unchanged activity. He did not study the problem of reserve capillaries in the presence of various states of the circulation. Therefore the existence of reserve capillaries in the lungs can be considered as established.

Increase in the venous pressure is one of the most effective means by which reserve capillaries can be opened in the larger circuit. In human beings this can be demonstrated with surface capillaries of the skin¹⁶. Whether the opening of the capillaries induced by increased venous pressure is a passive phenomenon depending on the widening of the arterioles, or an active process, or whether chemical, physical or local reflex factors regulate their opening does not bear on the problem discussed here. The importance of the widening of the arterioles and the opening of new capillaries to the local maintenance and regulation of adequate peripheral blood flow in the presence of congestion in the peripheral veins has been repeatedly demonstrated and emphasized in recent years. We believe that *in progressive heart failure the pulmonary arterioles widen and a reserve capillary bed opens in the lungs, and that the mechanism of this process is governed by the same physiological laws as have been demonstrated in the peripheral circulation.* This concept is not only supported by a number of observations, but it explains several apparently contradictory and isolated observations previously not understood. Wearn and his associates¹⁷ observed that new capillaries appear regularly when back

pressure is induced in the pulmonary vein by pressure over the aorta. Such pressure is more efficacious in opening the capillaries than increasing the blood flow and the pulmonary arterial pressure with adrenalin. In rheumatic heart disease and arterial hypertension a retardation of the maximal velocity of the blood flow through the lungs may occur with a normal or only slightly reduced cardiac output. In the later stages of circulatory failure again the degree of retardation of the blood velocity in the lungs is more marked than the reduction of the volume blood flow, as judged from the oxygen utilization in the upper and lower extremities³. This apparent discrepancy between the velocity and volume flow can be explained only by an increase in the cross-sectional area of the capillary bed. Such an increase may occur (a) through the stretching of previously opened capillaries, or (b) through the opening of new capillaries. The first possibility is not supported by experiments, and furthermore would be a purposeless and harmful mechanism. It would result in an early and marked increase in the pulmonary and capillary arterial pressure, which would soon damage the right ventricle and lead to pulmonary edema. Instead of one row, two rows of red corpuscles would pass through the capillaries, and this in turn would make the exchange of blood gases incomplete. As early as 1876, Lichtheim¹⁸ showed that considerable occlusion of the left pulmonary artery fails to induce any appreciable alteration in the pressure of the right pulmonary artery or of the aorta. Lichtheim concluded, therefore, that the amount of blood flow-

ing through the right lung was unaltered. He attempted to explain his observations on the basis of a compensatory increase in the diameter of the pulmonary artery.

Increase in the cross-sectional area may occur without any appreciable elevation in the resistance of the arteriolar and capillary beds of the lungs. All of these observations, therefore, indicate directly or indirectly that the increased cross-section develops through a widening of the arterioles and an opening of the reserve capillaries. A progressive increase of the capillaries makes it possible to maintain a normal or approximately normal volume of blood flow through the lungs per unit of time without much added burden to the right side of the heart. It is probably this mechanism which makes it possible for the patient with heart disease to live fairly comfortably for many years.

The opening up of numerous new capillaries along the alveolar surface and the moderately increased capillary pressure must have an important effect on the shape and consistency of the alveoli, which explains the stiffening observed experimentally by von Basch and his pupils some fifty years ago¹⁹. This dilatation and stiffening of the alveoli increases the residual air, relatively or absolutely, depending on whether or not the residual air increases at the expense of the reserve air of the lung. These changes in turn are responsible for the early decrease in the vital capacity. The reduction in the vital capacity, therefore, is not dependent on the volume of the blood in the alveoli, but rather on the development of a firm

emphysema of the alveoli induced by the opening of new capillaries under normal or higher than normal tension

The increased blood volume in the lungs does not decrease the total air space but rather causes the diaphragm and bony thorax to assume a slightly inspiratory position, thus allowing space for the increased total blood volume

If one accepts this theory of the circulatory and respiratory mechanisms one can then clearly understand that the development of dyspnea in heart disease is primarily due to the active rôle of pulmonary arterioles and reserve capillaries and to a functional emphysema. It is also possible that loss of elasticity of the alveolar wall *per se* makes expiration difficult and thus adds to the subjective sensation of dyspnea. In the finer analysis of the mechanism of dyspnea, reflexes between the lungs and the respiratory center activated by the changes just described play an important rôle. Numerous animal experiments reported in the literature also support the contention that *dyspnea in the early stage of circulatory failure is produced through nervous communications between the pulmonary system and the medulla and not by local chemical changes within the respiratory center*. Finally, the concept proposed not only brings into harmony the apparent contradictory findings referable to the pulmonary circulation but also offers a rational explanation for the fact, repeatedly demonstrated experimentally on animals since Lichtheim's original studies¹⁸, that the peripheral circulation may be normal despite changes in the pulmonary circulation

and in the alveoli and pulmonary reflexes

III. LATER STAGES OF CIRCULATORY FAILURE

In contrast to the early stages of circulatory failure, the later stages exhibit numerous *clinical manifestations*. With the progress of the dysfunction of the left ventricle, symptoms and signs of "congestive failure" gradually appear with cyanosis, râles over the base of the lungs, hydrothorax, dyspnea after slight or no exertion, orthopnea, increasing engorgement of the veins of the larger circuit, enlarged liver, ascites, peripheral edema and other well recognized clinical manifestations. Considerable variations occur clinically both in the appearance and the combination of these manifestations.

If one computes the various aspects of the circulation that have been *measured quantitatively in man*, one frequently finds the following sequence of changes. The vital capacity and the velocity of the blood flow become increasingly diminished²⁰. These two measurements may deviate 100 per cent or more from their normal values. With these marked changes comes a tendency to a decreased cardiac output of blood. The decrease in the blood volume flow through the lungs is normally not as marked as the degree of slowing of blood flow. Simultaneously, the peripheral venous pressure rises steadily above normal values. Greater and greater amounts of oxygen are utilized in the capillary blood, which, while the body is in the upright position, may reach oxygen values of as high as 16 to 17 volumes

per cent after slight exertion⁸. If the congestion in the lungs is marked, difficulty in the aeration of the blood reduces the oxygen saturation of the arterial blood. Only when the peripheral adaptations of the larger circulation have been exhausted do there develop, rather late in the natural course of circulatory failure, physicochemical disturbances of the blood, such as an increased lactic acid content, an altered buffer capacity, and changes in the hydrogen ion concentration. When these changes appear even at rest, the tissues of the entire body are severely affected in the performance of their necessary functions. Disturbances in the local or peripheral vasomotor reflexes are then an expression of extreme failure of the circulation.

The concept outlined in the previous chapter may be expanded even further, on the basis of the clinical observations and the quantitative measurements of the circulation during moderate or severe failure described above, in an attempt to obtain a more complete insight into the sequence of events. As the cardiac dysfunction progresses, the pressure in the pulmonary vein must rise further. This produces further compensatory dilatation of the pulmonary arteriolar system and hence an increase in the number of open capillaries. At the same time, in order that an adequate amount of blood should flow through the lungs, the pressure in the capillary bed must increase to correspond to the elevated pressure in the pulmonary vein. Considerable increase in the capillary pressure may occur without necessitating an increase of pressure in the pulmonary artery, since the widening of the

arterioles means that a relatively high arteriolar pressure is exerted increasingly on the capillaries, thus establishing an optimal or almost optimal pressure gradient between the capillaries and veins. In the previous study of the peripheral circulation²¹ it was shown that by inducing a relaxation of the arterioles the capillary pressure might rise to such high values as from 46 to 65 mm. in normal subjects, and from 60 to 150 mm. in patients with hypertension. By analogy, it is possible that the pulmonary capillary pressure might rise to about 20 mm. of mercury through arteriolar regulation. Only when the compensatory arteriolar pressure is exhausted will the pulmonary arterial pressure have to rise to correspond to a further increase in the venous pressure. With these progressive changes in the pulmonary circuit, there must be an increasing stiffening of the alveoli and an increase in the total volume of blood in the lungs. This is obviously present, as indicated by post mortem observation. The diaphragm tends to fall, and thus, partly for mechanical, partly for nervous reasons, the rapid, shallow respiration of the cardiac patient becomes necessary. Obviously, changes in the lung function due to pathologic alterations in the pulmonary circulation are, disregarding chemical disturbances of the blood, the primary factors in the respiratory difficulty. The dyspnea of the cardiac patient at this stage is still a local pulmonary problem. (The reflex interrelation between the changes in the lungs and the respiratory center cannot be entered into here). Thus the cardiac patient with severe primary disturbances in the pulmonary

circulation behaves to a certain extent not dissimilarly to the patient with acute emphysema. This concept is further supported by the occurrence in the cardiac patient of a distinctive type of respiration, the inspiratory position of the thorax, and the low diaphragm which often retracts the lower costal margins during inspiration. It explains also why cardiac dyspnea is often associated with expiratory difficulties in contrast to the dyspnea which develops in patients without heart disease after central stimulation. In patients with emphysema the changes in the lungs are independent of the circulation; in cardiac patients they are secondary to it.

There is another important factor in circulatory failure. The pressure in the pulmonary vein, both in normal subjects and in patients with circulatory failure, depends on gravity. Just as in the larger circuit, gravity increases the pulmonary venous pressure progressively below the level of the left auricle. As long as the circulation is normal this factor plays no obvious rôle. However, if, as in advanced failure, the pressure in the left auricle increases considerably, the situation becomes quite different. Under such conditions the pressure over the lower portion of the pulmonary vein must be considerably higher than over the upper portion of the lungs. Indeed, over the base it may become so high that neither the arteriolar nor the arterial pulmonary pressure can raise the capillary pressure sufficiently to insure an adequate capillary blood flow. Considerable slowing of the blood flow in the base of the lungs must occur at this stage, while the flow over

the upper portion of the lung must be more rapid. Finally, a stagnation of the blood flow results in "sedimentation of the blood" in the hypostatic portion of the lung leading finally to transudation of the serum. This "sedimentation of the blood" can be demonstrated by simple experiments in rabbits which are susceptible to postural changes from horizontal to upright position. It is this mechanism that produces clinical signs of pulmonary congestion.

Obviously, with the approach of pulmonary congestion, the vital capacity is diminished not only by the factors discussed in the previous section, but by the encroachment of stagnant blood on the alveolar spaces. This explains why measurements of the lung volume in this stage show a diminution of the total air spaces as well as of the residual air of the lungs¹⁰.

The orthopnea in cardiac patients with clinical evidence of pulmonary engorgement, prolonged velocity, lowered vital capacity but no elevation in the venous pressure, is due partly to the same causes as emphysema or asthma, partly to the fact that upright posture may elevate a considerable portion of the lungs and make possible the maintenance of the pulmonary blood flow with less strain on the right side of the heart²².

The consideration outlined clearly suggests the possibility that a *normal or decreased amount of blood may flow through the lungs under entirely different pressure relations within the pulmonary circuit. Thus the same minute volume of blood flow may represent different burdens for the right ventricle in different states of the cir-*

culation This explains also the hitherto paradoxical observations that digitalis occasionally may benefit the patient without materially altering the cardiac output or velocity of pulmonary blood flow^{4,23}. *The measurement of the amount of blood flow, without knowledge of the pressure in the pulmonary circuit, gives no indication of the energy expended by the right ventricle to maintain this blood flow.* We are dealing here with a mechanism somewhat similar to that of arterial hypertension of the larger circuit⁵.

With an embarrassment of the right ventricle which, depending on numerous factors, may occur at various stages of the pulmonary circulatory disturbance, the peripheral venous pressure increases considerably. There is also a definite slowing of the venous blood flow. The velocity of the arterial blood is not sufficiently known at present. However, certain studies indicate that it is slower in congestive failure²⁴. Considering, however, that as far as can be ascertained, the diameters of the large arteries do not show gross alterations in congestive failure, that the arterial blood pressure frequently remains unaltered; and that the blood volume and flow may be normal or lowered, one may justifiably conclude that the *slowing of the blood flow in the arterial system, if present, must be less than in the venous system.* Furthermore, as has been observed in a group of patients with advanced circulatory failure and venous congestion, the volume flow of blood to the legs may be normal and the arterial blood pressure unaltered. Thus the volume and ve-

locity of the blood flow through the arterial system may be normal even when there is a considerable slowing in the venous system. This is substantiated by the fact that in patients whose arterial blood pressure was normal and whose venous pressure was considerably elevated up to the time of impending collapse of the circulation, post mortem examination shows a normal diameter of the aorta and large arteries but a marked increase in the diameters of the vena cava and other large veins. If during life a compensatory constriction of the arteries occurs, a rational possibility neither proved at present nor demonstrable by post mortem observations, such a mechanism would tend to maintain a normal velocity in the arterial system. The aorta could not play an active rôle in such a mechanism as it is incapable of active constriction or dilatation²⁵. These considerations again bring out the following perhaps obvious, but nevertheless not fully appreciated facts concerning circulatory failure. (a) *although in a given time the total amount of blood flowing through a cross-sectional area of the larger arteries must be the same as that in the large veins; nevertheless, because of the independence and variety of the changes in the diameter of the cross-sectional areas in the venous and arterial systems, an abnormal deviation of the velocity of blood in the venous system may develop quite independently of any changes in the velocity of the arterial system,* (b) *changes in pressure in the arterial and venous systems and velocity are to a considerable extent independent.* These concepts are a rational explanation of

the fact that the arterial pressure, regardless of the degree of circulatory failure, may be normal, lowered, or slightly elevated even at a time when venous engorgement exists

Increased venous pressure has an important effect on the capillary circulation which performs the basic tasks of the blood and circulation both in the lungs and in the periphery. As described previously, it has been repeatedly demonstrated in animals and also in man that a sensitive regulation makes it possible that an optimal capillary circulation is maintained even in the presence of a gradually increasing venous pressure. Widening of the arterioles, through nervous reflexes, chemical regulation, or elevation of the arterial blood pressure, plays a dominant rôle in maintaining this regulation. The opening of new capillaries and increased oxygen utilization are then perhaps further consequences of, rather than independent processes in, the changes that follow venous engorgement.

In the presence of severe venous engorgement the capillary pressure inevitably rises. *Thus the capillaries of the patient with congestive heart failure are always under abnormal pressure wherever the venous pressure is elevated. The velocity of the capillary blood flow is independent of the capillary pressure, and is to a certain extent determined by the functional capacity of the left ventricle.* Thus, for example, we have evidence that in hemiplegia the capillary pressure over the paralyzed side is often increased, both relatively and absolutely, with the presence of increased velocity of blood flow⁶². *The balance between the*

functional capacity of the left ventricle, and the velocity of the capillary blood flow on the one hand, and the degree of elevation of the capillary pressure on the other, has a fundamental relationship to cellular nutrition and function. High capillary pressure, and a blood flow low in volume and velocity, such as occur in numerous instances of congestive failure, are a combination seriously damaging to tissue function. It produces not only a "passive congestion" and an edema *per se*—but as a result of disturbances of the internal respiration between the capillary blood and tissue cells, specific chemical substances, depending on the organs involved, appear in abnormal quantity in the blood stream. In these disturbances of tissue functions ischemia and anoxemia play important rôles, but they seldom occur without the presence of high capillary pressure and slow blood flow. Some substances, like histamine, will further specifically damage the capillary system. Others, like lactic and other acids, will increase the dyspnea through central stimulation. At this stage central chemical stimulation, in addition to the pulmonary reflexes, plays an important rôle in the production of cardiac dyspnea. Circulatory damage to the liver will completely upset the water metabolism. Circulatory changes in the kidney and other organs will break the sensitive and vital mechanism that maintains a constant acid-base equilibrium in the blood and tissues. Thus that stage of circulatory failure is now reached when the localized disease of the heart becomes a grave and extensive disease of metabolism, leading to death.

IV. CERTAIN APPLICATIONS OF THE CONCEPT PRESENTED

It has been suggested in this discussion that the simultaneous consideration of the pressure relationships in the veins, capillaries, arterioles and arteries, of the volume and velocity of blood flow, and of the permeability of the capillary system in the pulmonary and peripheral circulation together with the oxygen carrying capacity of the blood and the oxygen requirement of tissue, clarifies considerably our understanding of the clinical manifestations of heart failure. The relationship between these and other bodily functions during progressive heart disease has been computed from a series of observations and studies on a large group of patients with heart disease. Yet such a schematic presentation would carry false implications unless certain reservations were made.

Obviously not every patient with heart disease will proceed through all the stages described. Observations of the types and causes of death in cardiac patients reveal that a relatively small group of patients die in the last stage of the progressive congestive failure. Death frequently occurs abruptly at earlier stages because of precipitated arrhythmias of the heart, coronary occlusions, embolism or other vascular accidents, and uremia. Pulmonary congestion predisposes to bronchopneumonia and the added burden of this or other infections, for obvious reasons, is responsible for the death of another large percentage of cases. There is, finally, a group of patients in whom apparently none of the above factors are active. These patients, although the circulatory func-

tions are still fairly well sustained, exhibit sudden changes in clinical appearance and die within a few hours. A number develop a rapid pulse, low blood pressure, cold skin, dyspnea, abnormal vasomotor reflexes and die with clinical evidence of peripheral vasomotor collapse and shock. One wonders whether in such instances the long persisting dyspnea, cardiac pain, rapid heart rate and other factors subject the central nervous system to an abnormal bombardment, thus causing death through a failure of the vasomotor and perhaps other nerve centers rather than through extreme congestive circulatory failure.

In applying this concept of circulatory failure to different types of heart disease the *time element* and the *nature of the cardiac lesion* should always be considered. A few examples of this will be briefly outlined, as these factors with the physiological principles presented will clarify the variations in the clinical course of circulatory failure in different types of heart disease. In the *mitral stenosis* of rheumatic fever the disturbance in the pulmonary circuit develops rather slowly and hence the right ventricle is considerably embarrassed when the pulmonary engorgement reaches a severe level. The simultaneous failure of the right side of the heart at this stage reduces the pulmonary pressure. There is thus a fairly definite relation between the pulmonary and peripheral congestion. In *arterial hypertension and aortic insufficiency*, on the other hand, an appreciable rise of pressure in the pulmonary vein occurs relatively late and only when there is a failure of the left ventricle. Hence

the engorgement and disturbance in the pulmonary circuit develop rapidly and at a period when the right ventricle has still a normal functional capacity. For this reason, evidence of pulmonary circulatory embarrassment with congestion, dyspnea, orthopnea and right hydrothorax are observed frequently in these patients in conjunction with fairly normal peripheral circulation. The same consideration bears closely on the occurrence of paroxysmal dyspnea with or without bronchial asthma early in this type of circulatory failure; and also explains a frequent clinical observation that with the onset of failure of the peripheral circulation these paroxysms frequently disappear. The onset of failure of the right side of the heart prevents the maximal elevation of the capillary pressure in the lungs and shunts a part of the blood into the periphery. As a result, the disproportion between the pressure in the pulmonary and peripheral circulation decreases and, for this reason, the patient improves subjectively and the dyspnea and orthopnea often become less. Also the state of the circulation is less favorable to the development of asthma and of right hydrothorax.

Not infrequently with the development of dependent edema and ascites, the hydrothorax disappears. Recently we observed, in the few instances studied, that with the onset of edema and ascites the velocity of blood flow through the pulmonary circuit increased and subjectively the patient felt better²³.

In accordance with the concept, it is obvious why a patient with pure *tricuspid insufficiency* may be less in-

capacitated with a higher venous pressure and more cyanosis than a patient with circulatory failure due to syphilitic aortic insufficiency. The pulmonary embarrassment in this condition is less, and although the venous pressure is high, the volume flow and velocity may be fairly well maintained, due to the fact that the left ventricle is efficient.

In the circulatory failure associated with preponderant embarrassment of the right or left ventricle, such as occurs in rheumatic, syphilitic and hypertensive heart disease, the disturbances in the circulation, for reasons discussed above, occur more in one portion of the vascular bed than in others. In the myocardial failure which accompanies *aging* there appears clinically a fairly *parallel failure* of both ventricles and thus the disturbances in the pulmonary and peripheral circulation tend also to be parallel. Since aging processes impair the reserve functions of all organs, including the brain, the efforts of senile patients are not apt to be out of proportion to the functional capacity of the heart. These are probably the chief reasons why a number of old people exhibit a considerable restriction in functional capacity without a clinical picture of marked congestive failure. Thus "dry failure" is not necessarily the expression of a better circulatory efficiency than congestive failure. Naturally, if through aging processes the blood supply of one ventricle, especially of the left, is more impaired than the other, the development of one or the other type of congestive circulatory failure occurs.

The prognostic significance of individual symptoms and signs of circulatory failure can be estimated only if the underlying mechanism is understood. Dyspnea, hydrothorax, cyanosis, edema and other manifestations may result from various combinations of factors and therefore the same symptom in different patients or in the same patient at different times may have a varying significance. Another reason why a single clinical manifestation has, as mentioned before, no standard significance, is that certain extracardiac factors may play a fundamental rôle in the development of the same sign. For example, the occurrence of infection during early circulatory failure may damage the peripheral arterioles, thus leading to increased capillary pressure without venous engorgement or edema. In another instance, loss of protein due to kidney damage may hasten the development of edema in a stage of circulatory failure which by itself would not produce this sign. Right hydrothorax may be the result of pulmonary engorgement, or in other instances to local pressure on the azygos vein due to aneurysm of the aorta or dilatation of the auricles or ventricles.

Numerous other specific applications of the concept may be given; but the purpose of this presentation is not a detailed analysis of the various phases, symptoms and signs of circulatory failure, but rather the interpretation of those essential clinical and laboratory observations which are of practical importance to the physician in interpreting rationally the history and physical signs of the patient. The proper use of the principles empha-

sized should make diagnosis, prognosis and therapy more accurate. It is hoped that investigations in progress will yield additional facts to fill out the portion of this discussion at present unsupported by observations on patients.

SUMMARY AND CONCLUSIONS

1. On the basis of a series of investigations and clinical observations on patients, a concept of progressive circulatory failure has been formulated. This concept brings into harmony hitherto uncoordinated and apparently contradictory observations. It offers a rational and more exact interpretation of the clinical manifestations of circulatory failure associated with cardiovascular diseases.

2. The interrelations between pressure, volume and velocity of blood in various portions of the pulmonary and larger circulation and in turn their relations to other bodily changes in various stages of circulatory failure are discussed. The regulatory adjustments are so complex that simultaneous measurements of several aspects of the circulation are essential to an accurate analysis of clinical symptoms and signs.

3. In the early stages of circulatory failure marked alterations occur in the pulmonary circulation, while the larger circulation is normally maintained. The elevated pulmonary venous pressure is primarily responsible for the disturbed pulmonary circulation. Recent advances in the physiology of the pulmonary circulation substantiate the concept of the beneficial regulatory functions of the pulmonary

arteriolar and capillary system. The same volume or velocity of blood flow through the lungs in various stages of failure may represent different burdens for the right ventricle and the ventilative mechanism of the lungs, and hence may be associated with varied clinical manifestations.

4 The dyspnea of early circulatory failure depends to a large extent on the altered function of the alveoli of the lung, which is secondary to changes and regulatory adjustments in the lesser circulation. These pulmonary changes set up reflexes be-

tween the lungs and the respiratory center. Chemical stimulation of the respiratory center is present only in the late stage of congestive failure of the larger circulation.

5 In failure of the larger circulation changes in pressure and velocity of blood flow may develop independently in the arteries and veins.

6 The combination of elevated capillary pressure with decreased velocity and volume flow are the chief factors responsible for damage of cell nutrition in the later stages of circulatory failure.

Dissecting Aneurysms of the Aorta, Including the Traumatic Type: Three Case Reports*

By PAUL C SAMSON, M D,** *Chicago, Ill*

IN DEALING with dissecting aneurysms of the aorta one is confronted with the strange clinical paradox, that a condition which has such marked pathology is so rarely diagnosed during life. Since the lesion was first accurately described by Morgagni¹ in 1761 there have been over four hundred cases, either described or mentioned in the literature. From English and German sources, Gager² has collected only seven cases diagnosed during life. (See Swaine,³ Wyss,⁴ Mager,⁵ Davy and Gates,⁶ Moosberger,⁷ Finny,⁸ and Osler.⁹ Etling¹⁰ refers to five more cases all of the traumatic type, which were diagnosed before death and reports rather fully his own case of traumatic aneurysm of the aorta diagnosed while the patient was still living. (See Grant,^{10a} Bieton,^{10b} Gils,^{10c} Boyer,^{10d} and Marone^{10e}.) To this small group should be added a case diagnosed antemortem by Dr. E. E. Irons, which is being published. The following re-

view contains another case which was diagnosed before death.

Although the term "dissecting" has been popularly ascribed to Laennec, it has been shown by Peacock¹¹ and others that M. Maunoir and Allan Burns both preceded Laennec in their use of the term.

The etiology is varied. 1 Mechanical injury, trauma from without, of special importance in the present review. 2 "Mesarteritis dessicans," first emphasized by Babes and Mionescu¹² as a disease entity and later supported by Whitman and Stein.¹³ This is probably the same condition referred to by Shennan and Pirie¹⁴ in their paper on the subject, although it is not specifically named. There seems to be a number of cases in which such a condition exists. The underlying cause of mesarteritis dessicans is not fully understood. In some cases it seems to be purely a degenerative process and in others an acute streptococcus or staphylococcus infection appears to play a rôle. The most important microscopic changes noted by the above authors are fatty or hyaline degeneration of the interlamellar connective tissue, thinning and rupture of the elastic fibers, atrophy of the smooth muscle. It is believed that where the underly-

ing cause is pure degeneration, increased stress on the medial tissues because of greater distance from the lumen of the vessel, and lessened blood supply, are important factors. 3 A group of factors causing a sudden severe strain on the cardiovascular system, and presumably increased blood pressure excitement, extreme emotional upset, heavy meals, straining and over-exertion in persons not used to great muscular effort. In practically every case of this type a generalized arteriosclerosis forms the common substratum, with such agents acting as precipitating factors. Hypertension, chronic or acute, *per se*, while not a frequent cause of dissecting aneurysm, is implicated at times. Thus Von Schnurbein¹⁵ in an analysis of ninety-one cases found that in two, hypertension was the sole causative agent, while it was of primary importance in seventeen more. 4 Congenital. The underlying anomalies include a, thymic-lymphatic constitution with aortic and cardiac hypoplasia, b, aortic stenosis; c, dilatation of the aorta at its origin combined with a thinning of the wall. Microscopically the intima is healthy in these patients. They comprise the youngest group in whom dissecting aneurysms occur.

While it is conceded by most authorities that forces causing a sudden cardiovascular strain and increase in blood pressure do not injure the normal aortic wall of a normal individual, it is believed that such forces may precipitate a dissecting aneurysm in persons having congenital cardiac or aortic anomalies of the type mentioned above.

Most authorities consider syphilis as a rare cause of dissecting aneurysm. Von Schnurbein¹⁵ found only one case in which he thought that syphilis was responsible. Further emphasis has been added by Loeschke.¹⁶ He states that syphilis rarely if ever is the direct cause of a dissecting aneurysm, but that it may, if present in conjunction with an aneurysm of this type, aggravate the aneurysm considerably. It is true that there have been several case reports of dissecting aneurysm where syphilis was present, but the number is small enough so that the presence of syphilis might be considered coincidental. It seems probable that a luetic mesaortitis, through an interference with the blood supply leads to a degeneration of the medial fibers, and a somewhat displaced arrangement, saccular aneurysms being the sequel instead of the dissecting type.

The symptomatology has been excellently summarized by Gager.¹⁷ The mode of onset is sudden, following excitement, exertion, or injury. The pain is outstanding, sharp and tearing, generally of higher segmental distribution than in coronary thrombosis. There may or may not be radiation. Because of the progressiveness of the pain and the disturbance of circulation in other organs, a good hint to the diagnosis can be gained. There may be pain in the back, possibly caused by a tearing of the intercostal arteries. Pain in the abdomen and groins from an interference with the abdominal aorta and its branches. There may be a tearing of the renal arteries. There may be a tearing of the iliac arteries. There may be a tearing of the femoral arteries. There may be a tearing of the popliteal arteries. There may be a tearing of the tibial arteries. There may be a tearing of the peroneal arteries. There may be a tearing of the plantar arteries. There may be a tearing of the digital arteries. There may be a tearing of the capillary arteries. There may be a tearing of the venous system. There may be a tearing of the lymphatic system. There may be a tearing of the nervous system. There may be a tearing of the endocrine system. There may be a tearing of the reproductive system. There may be a tearing of the excretory system. There may be a tearing of the integumentary system. There may be a tearing of the sensory system. There may be a tearing of the motor system. There may be a tearing of the autonomic system. There may be a tearing of the immune system. There may be a tearing of the endocrine system. There may be a tearing of the reproductive system. There may be a tearing of the excretory system. There may be a tearing of the integumentary system. There may be a tearing of the sensory system. There may be a tearing of the motor system. There may be a tearing of the autonomic system. There may be a tearing of the immune system.

feet may follow circulatory disturbance (See Davy and Gates,⁶ Dickinson,¹⁷ Swaine,⁸ Oliver,¹⁸ and Peabody¹⁹) Severe continued pain between the shoulder blades combined with substernal pain is a rather constant finding Findings on examination may include a harsh rumbling bellows' sound over the aorta in the chest or abdomen, a sudden increase in the retro-manubrial dullness, adventitious swellings, and an associated inequality in the blood pressure readings and in the pulses on the two sides of the body X-ray corroboration is important

The diagnosis is based on a study of the symptomatology, and of the past history in an effort to discover an exciting cause When the condition is suspected it may be necessary to make a differential diagnosis from coronary thrombosis because the type of pain is often similar in the two conditions In dissecting aneurysm there is usually a continued cardiac competence and a lack of typical lung findings The blood pressure generally continues at its accustomed level at least for a time, and may be unequal on the two sides of the body With continued dissection the pain has a progressive character not found in coronary thrombosis Electrocardiography may show only various types of irregularities The diagnosis of this condition while the patient is still living is important, because a certain number go on to recovery This can be aided by proper supportive measures if the aneurysm is recognized On the other hand a wrong diagnosis may lead to an exploratory laparotomy, or some other course of treatment equally harmful

The prognosis is grave Crowell²⁰ has estimated that about 65 per cent die almost immediately from complete rupture In another 10 to 15 per cent a sudden death usually occurs in a few days The small number surviving this period have a good chance for recovery In these, the aneurysm may rupture back into the aorta, or more rarely, become a closed sac filled with a clot In both cases the false channel eventually becomes lined with intima and a "healed" aneurysm is the result, usually without sign or symptom Obliteration of the false channel by scar tissue proliferation is extremely rare

The intimal laceration usually occurs in that portion of the aorta which is subjected to the most strain from the constant flow of blood, namely in the origin and ascending portions In Peacock's¹¹ series of eighty cases, over two-thirds showed lacerations in this region From a prognostic point of view these are the gravest Not only are the symptoms severe, but a great majority terminate in a short time with rupture into the pericardial sac In general it may be said that the farther along the aorta the aneurysm occurs, the less alarming are the symptoms and the better is the prognosis for life At the origin of the aorta and in the ascending portion and arch, the initial intimal laceration of spontaneous dissecting aneurysm is usually transverse Elsewhere it is usually longitudinal Practically all of the intimal lacerations of traumatic dissecting aneurysm are transverse or slightly oblique, regardless of where they are found

Traumatic aneurysms of the aorta are practically all dissecting While relatively more rare than the sponta-

neous type, they are being seen somewhat more frequently due to the greater number of industrial and automobile accidents occurring at the present time. About one hundred cases have been reported since 1895. War injuries have been responsible for a number. Although Hubener²¹ has stated that in the case of a traumatic intimal rip which has healed without dissection there can be a saccular aneurysm formed from the stretching of the scar by the constant stress of blood pressure, it is hard to conceive that bodily reparative processes cannot, by connective tissue proliferation, reinforce such an area so that it will not become sacculated. However constantly repeated low grade traumatism may lead to a saccular formation. A case reported by McFadzean²² showed four saccular aneurysms of the abdominal aorta and common iliacs in contrast to a relatively healthy thoracic aorta. This occurred in an old man who had for years been a trapeze and hard bar performer. There was no history of lues and no evidence of it at autopsy. In this case it was considered that the long continued traumatization of the vessels between the bar and the vertebrae or pelvic brim was the sole causative agent.

Traumatic dissecting aneurysm may occur in a healthy aorta, providing the causative force is severe enough. Indeed under certain circumstances a healthy aorta may be torn completely across. Such a case was reported by Copeland,²³ in which there was no external evidence of the cause of death. The reason for the complete rupture was not entirely clear. It might have been due to the tearing action of a

coup. Obviously a force of less intensity is necessary to produce a traumatic dissecting aneurysm in a sclerotic and atheromatous aorta. In these cases the site of laceration seems to be the 'hyaline fibroid' lesion described by Adam,²⁴ which is closely attached to the media in a scar-like formation, and not the sclerotic plaque of the intima which is somewhat loosened from the media.

Traumatic dissecting aneurysm of the aorta is generally formed at the time of the accident or immediately following. It may be produced by several types of injuries. A severe blow on the chest by a large blunt force may be the causative factor. Kuhn²⁵ had under his care a man who was struck in the chest by a block of wood thrown from a buzz saw. A crushing injury of the chest with the fracture of several ribs, such as sustained in an auto accident or in a fall, may be responsible. (See cases below). Shennan has also reported a case in which a fall caused a dissecting aneurysm. The individual struck the pavement, fracturing his clavicle and several ribs.

It has been shown that in traumatic dissecting aneurysm the initial intimal laceration is usually (a) at or near the attachment of the obliterated ductus Botalli, (b) just above the aortic valves. It is often the posterior part of the wall that is injured. It will be remembered that the ligamentum arteriosum joins the aorta very near the root of the left lung, and is closely related to the structure of the root. The whole structure is subject to the tearing action of the lungs when they expand and contract. The tearing action is especially marked when the lungs are expanded and the aorta is contracted.

point. The arch as a whole is further fixed by the great arterial trunks. In the post-mortem examination of many cases, it has seemed that the hinge-like action of this attachment was responsible for localizing the point of injury. This has been emphasized by Jaffe and Sternberg²⁷ and Shennan.²⁶ The former authors found that in aviators who had fallen from various heights, there were transverse aortic lacerations at or near this attachment. The anterior wall of the aorta is not as fixed as the posterior, and the latter may be crushed against the vertebral column, thus sustaining the brunt of the impact.

With regard to the medico-legal aspect, Kauffmann²⁸ maintains that dissecting aneurysms do not form as the immediate effect of an accident, and that the time elapsed is generally great enough to relieve an insurance company of any responsibility. He states that a large aneurysm noticed after an accident generally speaks against any relationship between the aneurysm and the accident. On the other hand, Etling¹⁰ has collected evidence to support the opposite view. The judgments rendered in his cases show that 1. Traumatism is admitted to be a cause of dissecting aortic aneurysm, 2. The lesion is very serious, 3. When it occurs while at work and is so diagnosed, it may constitute the basis for damage-suits and claims for compensation, 4. Treatment should be continued over several months before an amelioration of symptoms is hoped for, 5. When symptoms persist the lesion may be classified under the law allowing for accidents from work, 6. In point of gravity traumatic aneurysms

should be placed among the causes for permanent incapacity from work.

In at least one instance²⁹ in this country, a Supreme Court (here of Idaho) has ruled that when a sudden strain or injury on the part of an individual during the course of employment either causes a fatal dissecting aneurysm or aggravates one already present to such an extent that the patient dies, such a fatality constitutes a death from an accidental injury and is compensable.

CASE REPORTS

The first case is rather unusual. While not absolutely proven, it is believed that the dissecting aneurysm found at autopsy was of traumatic origin. It was undiagnosed during life, was symptomless, and played no rôle in the death of the patient. The aneurysm had occurred sometime previously, probably dating back five years to the time of the patient's rather severe injury. While it ended in a blind pocket and had not ruptured back into the aorta, the aneurysm was "healed" in the sense that it was entirely lined by endothelium and had a small blood stream functioning through a canalized thrombus which supplied the superior mesenteric and left renal arteries.

CASE 1. C. W., a white man, age 73, until five years before his death had enjoyed excellent health. At that time, in the fall of 1925, he was in an automobile accident. The hospital report, furnished by Mercy Hospital, Oshkosh, Wisconsin, showed that he was admitted in an unconscious condition. General examination and x-ray, revealed an oblique fracture of the right clavicle with displacement, three transverse fractures of the sternum in fair position, and fractures of the mid-portions of the 3rd and 4th ribs on the right.

While in the hospital the patient had some blood stained sputum, but no frank hemoptysis. The first urine specimen was smoky and full of microscopic blood. Albumin and many casts were present. The blood Wassermann was negative. There was a temperature rise to at least 100° F, nearly every day. The patient was in the hospital three weeks. He was not well following discharge, but suffered considerable pain in his hips and lower spine. In Dec., 1926, he went to the Mayo Clinic. The abstracted record shows that he was suffering from a hypertrophic arthritis of the hip joints. His fractures had healed. There was some hypertension and a moderate secondary anemia. Urinalysis and blood Wassermann were negative. There was a generalized sclerosis of the pelvic vessels. No heart disease was reported. According to his daughter he had not suffered any shortness of breath or pain up to this time. Several months later he became weak and short of breath after walking against a wind. This passed off with rest. In January, 1930, his ankles began to swell and his liver became enlarged. A week of low grade abdominal pain and slight shortness of breath was followed by an attack of extreme dyspnea, and a sudden excruciating epigastric pain. This lasted some time. After a month's sickness he recovered temporarily and started to do a little work again. He did not limit himself sufficiently, and in May, 1930, he had a similar attack. He never completely recovered, and for the next five months before his admission to Presbyterian Hospital, he suffered considerably from dyspnea and dull epigastric pain. Latterly he took morphine nightly for rest and was not able to leave the house. He could lie down but rested more easily on pillows.

He was admitted in August, 1930, on the service of Dr R C Brown. There was grave cardiac decompensation. The heart was enlarged, rate 60, with marked irregularity and a moderate pulse deficit. His respirations were labored and of Cheyne-Stokes' type. There were a few moist râles at the bases, the liver was enlarged and the lower extremity edema reached to the knees. There was a moderate secondary anemia. His blood chemistry was normal. The blood

pressure was 168 over 102. The urine admission showed albumin and casts, which however, cleared up before discharge. A phenolsulphonphthalein test showed a 60 per cent excretion in three hours. The electrocardiogram showed myocardial damage: ventricular extra-systoles. He was in hospital for two and one half weeks on usual supportive régime and showed marked clinical improvement. He remained at home for five weeks. On re-admission all previous symptoms were aggravated and grew gradually worse until his death days after admission. His rather sudden death was typically cardiac. The clinical diagnosis was arteriosclerosis with moderate hypertension, chronic fibrous myocardium and cardiac decompensation, and general anasarca.

Post-mortem Examination (Dr C H felbach) "Anatomical Diagnosis: Marked generalized arteriosclerosis, multiple infarcts of the myocardium, marked hypertrophy of the wall of the left ventricle, chronic passive hyperemia, marked anasarca of the lower extremities, ascites and bilateral hydrothorax, arteriosclerotic atrophy of the kidneys, old dissecting aneurysm (traumatic) of the thoracic portion of the aorta.

"The aorta was opened along the dorsal wall. The scissors, cutting from above downward, entered a sac. The beginning of the sac was 14 cm above the mouth of the celiac axis. At its upper end there was a transverse groove in the lining of the sac about 1 mm wide. The main character of the aorta consisted of a narrow curved dissection that admitted a thin metal ruler 1 cm wide, the upper opening of the dissection being at least four-fifths of a cross-section of the aorta. The narrow true posterior dissection of the aorta was on the right side of the sac (Figure 1*). The lower end of the dissection channel was at the mouth of the renal artery, and into it also opened the posterior arteries and the celiac axis. The dissection was about 16 cm long, the proximal part being filled with fluid blood clot, the distal 10 cm was occupied by a

*The photographs are by Mr F H felbach, photographer at Rush Medical College, under the supervision of Dr C H felbach.

FIG 1 The true channel of the aorta is at the right side and the opening is held together artificially. The proximal portion of the aneurysmal sac contained only fluid blood, whereas the distal portion, where it bulged slightly, is filled by a canalized thrombus. In the true channel of the aorta the mouth of the right renal artery is visible immediately adjoining the wall of the aneurysm near the distal end of the sac.

brown dry thrombus. The lining of the first part of the sac and of the rest of the aorta had the same color but in the former region there were no sclerotic plaques or fatty deposits, both of which were abundant elsewhere.

"The superior mesenteric and left renal arteries emptied into the aneurysm through the thrombus. The front wall of the aorta bulged on the left side for a distance of about 8 cm, and this was in the region of the brown thrombus.

"The transverse groove at the beginning of the aneurysm (see Figure 2) was slightly jagged and surrounding almost all of the aorta. At the opening of the aneurysm there was a thin ridge of tissue extending across a part of the right side.

"A cross-section through the aneurysm and the main channel of the aorta (see Figure 3) in its upper third, at about the level of the sixth intercostal branch, reveals a splitting of the media of the aorta into two parts, thus making up the wall of the aneurysm. The false channel is on the right. The same relations are illustrated in a cross-section (see Figure 4) through the lower third of the aneurysm showing on the right the canalized thrombus through which the blood stream supplying the superior mesenteric and left renal arteries was maintained."

Histology. In sections of the aorta proximal to the aneurysm, stained with hematoxylin and eosin, the sub-intimal layers are moderately thickened by hyalinized fibrous tissue. The nuclei are sparse and there are a few lime salt deposits. In sections stained with phosphotungstic-hematoxylin, the elastic fibers of the media are segmented. The adventitia is not changed in any noteworthy way.

In sections through the transverse groove at the beginning of the aneurysm, the con-

mal cavity, the wall is split into two unequal parts, the greater thickness being toward the aortic side. Nuclei are few in number and all tissues stain lightly. There is an intimal lime salt deposit on the aortic side of the wall only. Extending through the middle of the section is a layer of smooth muscle fibers. The unequal split is through this layer. There are a few broken elastic fibers on the aneurysmal side of the partition.

In cross-sections through the junction of the outer wall and the partition taken about 5 cm below the opening of the aneurysm, the media is of normal thickness on the aortic side. At the lateral edge of the aneurysm there is a split in the media, about one-third running in the wall of the aneurysm and about two-thirds running out into the partition. There is a reduplication of the partition wall. On the aortic side of the split are lime salt deposits.

In similar cross-sections taken just above the termination of the false channel, the wall of the aneurysm contains very few smooth muscle fibers, and there is a corresponding increase in the thickness of the smooth muscle coat in the partition. The dissection at this level, as judged by the small amount of involuntary muscle remaining, was very near the junction of the media and adventitia. In place of the smooth muscle fibers there is an intermediate zone in the wall of the aneurysm showing round cell infiltration and active fibroblastic proliferation. This is in the region which showed gross anterior bulging of the aneurysmal wall. Lime salt deposits are extensive. Elastic fibers are sparse.

In a few sections there is a small amount of perivascular round cell infiltration limited to the adventitia. *Triglyceride fat* is not found in sections stained with hematoxylin and eosin, but is present in the fat of the aorta.

FIG 2 Illustration of the transverse scar and the ridge of tissue stretching across part of the opening of the aneurysm. The lining of the first part of the aneurysm is irregular, but there are no fatty changes like those in the wall of the upper portion of the aorta or of the true passage.

tion with the daughter, did he have any symptoms indicative of a spontaneous dissecting aneurysm of the size found, in which there must have been a temporary but serious interference with the blood supply to the left kidney and small loops of bowel. Immediately following the accident the patient had a smoky hematuria, probably from the kidney. Hanser³⁰ has emphasized dissecting aneurysm as a cause of blood in the urine, of renal origin. The train of symptoms and the cardiac failure responsible for his death are explainable on the basis of the coronary thrombosis found at autopsy. The original intimal laceration was in the upper part of the descending thoracic aorta and was transverse. If the aneurysm had been present previously, it would have in all probability ruptured through at the time of the accident. There was no blood staining of the tissues in the neighborhood of the scar either microscopically or macroscopically. Under similar circumstances, if the indi-

vidual in question had been younger and without atherosclerosis, the diagnosis of *traumatic* dissecting aneurysm would have been unquestioned.

CASE 2 This case was also believed, from rather positive clinical and x-ray evidence, to have been one of traumatic dissecting aortic aneurysm, and was so diagnosed during life. There was no post-mortem proof, however. *History* Dr R. A. W., age 62, was admitted to the Presbyterian Hospital on the service of Dr. James B. Herrick in July, 1922. He complained of tachycardia, dyspnea on exertion, orthopnea, and swelling of the ankles.

Eleven years before at the age of 51, when previously perfectly well, he had fallen on his back from a height of ten feet. He was severely shaken up and following the fall he had hemoptysis for three weeks. During this time he suffered from a severe substernal pain and sense of oppression. The pain went through to his back. Later it became constant and aching.

A year after the accident he had his first attack of tachycardia, weakness and dyspnea, coming on suddenly while operating. Fluoroscopy showed a slightly dilated pulsating aorta. Two years after the accident x-ray showed a definite fusiform aneurysm.

of the descending thoracic aorta. There was no history of lues and repeated Wassermann examinations were negative. Three years after the accident the patient had a similar attack, again while operating. Between attacks he was symptom free. During the seven years previous to his admission to Presbyterian Hospital, he had attacks of tachycardia, coming on about once a month, generally without exertion. His blood pressure averaged about 160 over 100. There was a slight albuminuria discovered nine years before.

The patient had been able to work until May, 1922, in spite of his attacks, but at that time he had a particularly bad spell, associated with a dilated heart. He rested during the four months previous to his ad-

mission, but in spite of this there was a progressive increase in the severity of his symptoms.

On admission, general examination showed a somewhat enlarged heart, and an increase in the retromanubrial dullness. No murmurs were heard. There was a systolic retraction of the precordial interspaces. The liver was enlarged but there was no ascites. Some edema of the legs was present. Urinalysis showed albumin and casts. X-ray showed a fusiform dilatation of the descending thoracic aorta.

While in the hospital there was a progressive improvement, and the patient was discharged with a diagnosis of "healed" traumatic dissecting aneurysm of the descending thoracic aorta, adhesive pericarditis.

FIG 4 This is a transverse section through the distal third of the aneurysm illustrating the canalization of the large thrombus which occupies the false channel, and the splitting of the media to form the wall of the aneurysm. The aortic channel is on the left.

and pleuritis, chronic myocarditis with broken compensation, and chronic nephritis. The patient lived some time after discharge from the hospital

CASE 3 Through Dr E. R. LeCount it was learned that Dr. Roger T. Vaughan, Night Warden at Cook County Hospital, had diagnosed a case of spontaneous dissecting aneurysm of the aorta during life. Aside from the obvious interest attached to a rare diagnosis, this case is important because it illustrates, also, the all too frequent tendency to diagnose a perforated ulcer because of acute upper abdominal pain.

Case Summary J. H., a white male, age 49, was admitted to Cook County Hospital in December, 1921, at 6 P. M., after having been seen at home and sent in as a suspected case of perforated gastric ulcer. Previous to this time there had been trouble referable to the gastro-intestinal tract. However he had complained of palpitation on climbing stairs for about two months. Six weeks before the onset he had been treated at the Rush Dispensary for "heart trouble."

About five hours before admission and shortly after eating, he was suddenly seized with an agonizing knife-like pain, located principally in the epigastrium. It was constant, but waxed and waned in intensity. It doubled him up and he was very restless, rolling from side to side. The pain was something entirely new to him. He vomited several times during the afternoon, but had seen no blood. He was dizzy and covered with perspiration. Earlier, his distress had been aggravated by drinking hot water. On admission there was slight upper abdominal rigidity and moderate tenderness localized chiefly in the epigastrium. The pain was entirely out of proportion to these

rough to and fro pericardial friction rub was audible over the entire precordium. There was a retraction of the apical interspaces in systole. The lung examination was negative. On careful questioning it was elicited that the patient also had pain over the lower two or three ribs on both sides, radiating from back to front.

The conclusion drawn was that this was not a surgical abdominal condition. The absence of marked rigidity, tenderness, distension, and mass and the presence of practically normal peristaltic sounds failed to form the basis of any evidence of an intra-abdominal lesion.

The primary findings were severe pain in the epigastrium and lower chest, neuralgiform in character, sudden in onset, and lasting more or less constantly over a period of five hours, unequal pulses and unequal blood pressures. Along with the slight anemia this suggested a sudden accident in the chest. At his age the rupture of an aneurysm was the most likely possibility, and the relative slowness of a fatal termination suggested an aneurysm of the dissecting variety. There was no evidence of perforation into the peritoneal or pleural cavities. No aneurysmal findings such as bruit or pulsation were present. It was suspected then that the lesion was an aneurysm of the arteriosclerotic type affecting

mission prohibited such a procedure. In addition it was felt that the diagnosis was sufficiently secure on clinical grounds alone. Post-mortem examination was confirmatory.

Anatomic Diagnosis (Dr E R LeCount)

"Fresh dissecting aneurysm of the aorta, innominate and right common carotid arteries perforation into the pericardial sac, marked hemopericardium, slight left hemothorax, slight hemoperitoneum, slight hemorrhage into the tissues back of the aorta and around the innominate artery and vein, compressed right auricle and ventricle, edema and anemia of the lungs, edema and marked hyperemia of the liver, passive hyperemia of the kidneys and spleen."

Other items in the diagnosis have no bearing on the disease under discussion.

"The pericardial sac is completely filled with blood, most of which is clotted. The pulmonary artery is deeply furrowed by the pressure in front, and the right auricle and ventricle are partially collapsed. The hemorrhage has occurred from a rupture of the adventitia on the right side of the aorta. In addition to the pericardial hemorrhage, blood has seeped into the tissues just below the innominate vein and to the left of the innominate artery. There is a slightly turbid pale brown fluid in the left pleural cavity.

The wall of the aorta is split all the way down to 4 cm caudad to the renal arteries and the split extends in the other direction to the heart and is in the dorsal part of the wall. The wall of the abdominal aorta is thin, and occupying nearly all of the lining of this part, as well as of the common iliacs, are yellowish thickenings without lime. The dissection is continued into the innominate and right common carotid arteries, but these are the only branches so involved. The split in the innominate artery extends into the right common carotid artery for about 2 cm distal to the mouth, and here there is a transverse slit in the wall about 7 mm long, through which the lumen of the artery communicates with the aneurysm."

SUMMARY

1 In the foregoing review we have summarized what appear to be the most important features of dissecting aneurysm of the aorta, from a clinical and pathological standpoint.

2 The etiology, symptomatology, diagnosis, prognosis and pathology of dissecting aneurysm of the aorta are given.

3 Particular stress is laid upon traumatism as an etiologic agent, with a discussion of the probable relationships of the different mechanical and anatomic factors concerned.

4 Various medicolegal aspects of traumatic dissecting aneurysm of the aorta are presented.

5 Three new cases are reported, two of which were confirmed at autopsy.

Case 1, illustrated, was probably of traumatic origin. Case 2, probably also of traumatic origin, was diagnosed before death. There was no post-mortem examination. Case 3 was a proven case of spontaneous dissecting aneurysm of the aorta, diagnosed before death.

I am indebted to the following men for timely suggestions, and for permission to use material: Dr James B Herrick, Dr E R LeCount, Dr C W Apfelbach, Dr R C Brown, Dr Roger T Vaughan. Case records and abstracts were kindly furnished by Presbyterian Hospital, Chicago, Cook County Hospital, Chicago, Mercy Hospital, Oshkosh, Wisc., The Mayo Clinic, Rochester, Minn.

Clinical and Experimental Observations on the Treatment of Pernicious Anemia with Desiccated Stomach and with Liver Extract*†

By CYRUS C STURGIS, M D , F A C P , and RAPHAEL ISAACS, M D ,
F A C P , *Ann Arbor, Michigan*

INTRODUCTION

THE possibility that a defect in the stomach may be related to the etiology of pernicious anemia has been recognized for many years. This belief has been based upon a number of clinical facts, some of which have been established and confirmed by numerous observers. The most significant evidence suggesting this etiological relationship is that every patient, probably without exception, has at least a functional impairment of the stomach mucosa as indicated by the inability to secrete hydrochloric acid. This fact becomes even more significant now that it is known that hydrochloric acid is not secreted under the powerful stimulus of histamin injections, that the achlorhydria precedes all other known evidence of the disease, and that the acid does not appear in the gastric contents during a spontaneous or therapeutically induced remission. Evidence of an impaired function of the stomach mucosa, therefore, is the

earliest, the most constant, and the most persistent abnormality known to exist in a patient with the disease.

Additional suggestive data pointing to the rôle of the stomach in the causation of the disease, are to be found in the reported cases of patients who have had a total gastrectomy and who later developed the blood picture of pernicious anemia. This important evidence is based upon only rare observations, as the operation usually is performed for extensive carcinoma of the stomach, recurrences of the growth may confuse definite conclusions, and many patients do not survive a sufficient period of time to permit the development of the anemia.

Opinions concerning the importance of the stomach in the etiology of pernicious anemia have been based solely upon clinical observations until recently when Castle¹ reported his classical experiments, which appear to demonstrate conclusively that there is fundamental relationship between the anemia and a defect in the gastric secretion. This observer fed proteins in the form of 300 grams of slightly cooked Hamburg steak to normal persons and recovered it after it had been

†Read at the Baltimore Meeting of the American College of Physicians, March 27, 1931.

the sex, age, duration of present illness, red blood cell count prior to treatment and the dosage employed in treatment in the two groups is given in Table I

Preparations Used and Method of Administration—The desiccated stomach* was prepared by removing the fat and surrounding mesentery, and chopping the material very fine. This was then dried at a low temperature and the fat removed by repeatedly washing with petroleum benzine. One hundred grams of fresh stomach yielded an average of 13.3 grams (11.7 to 15.0 grams) of the dried, defatted, material. With the fat removed the material has very little odor and only

*Ventriculin (N.N.R.) prepared through cooperation with Parke, Davis and Company of Detroit

a slight taste. It is not soluble in water, but may be eaten, preferably in tomato juice, as one would a thick cereal. Lilly's Liver Extract was used throughout in the second group and in most instances was given in tomato juice, but also in water or orange juice. Usually both therapeutic agents were given to the patient midway between breakfast and lunch, but occasionally the dose was divided into two equal parts by giving a mid-morning and mid-afternoon portion.

The blood studies were made at the same time each day so that comparative observations could be recorded. For the reticulocyte counts, brilliant cresyl blue-Wright's stain preparations were made, 1000 cells being counted, except when there was any doubt, in which case 2,000 or more were enumer-

however, may persist in those patients who have advanced spinal cord changes, even though the red blood cell count becomes normal. It is possible that this may be explained by an impairment of the nervous control of the intestines. The characteristic glossitis which was present in over fifty per cent of this group of patients is usually readily controlled by the treatment. In a few patients, it has persisted in a mild degree, and occasionally there has been recurrence of the complaint after the blood has become normal.

Fever, Pulse Rate, Gain in Strength
Other striking manifestations of improvement are the disappearance of the

fever and tachycardia which are so commonly present when the anemia is severe, and a rapid gain in strength and sense of well being. Even when the anemia has been severe before treatment, the patient is usually able to become ambulatory within a week or two, and in an additional six to eight weeks may resume a normal life. Some patients have returned to their former laborious occupations, which have required more than an ordinary amount of physical strength and endurance.

Skin Changes Additional and constant evidence of improvement is a disappearance of the yellowish pallor which is present in all patients when

FIG 1 Shows average gain in body weight of 50 patients treated with Ventriculin, in weeks

the anemia is severe. This disappears as the blood bilirubin approaches normal, which is in about two or three weeks. It is interesting to note that within a few days after the treatment is begun, the pads of the fingers and palms, the chin, the cheeks and the tip of the nose become flushed. This reaction must be a vasomotor phenomenon as the flushing occurs before there is a demonstrable increase in the red blood cell count. The creases in the palm of the hands remain pale, however, and do not become red until the blood count is between $2\frac{1}{2}$ and 3 million red blood cells per cubic millimeter.

tract to keep their blood at a normal level. From our present experience, however, it is not possible to say that desiccated stomach is superior to liver in treating the neurological complications. In general it may be concluded that improvement in the minor neurological symptoms frequently occurs, but in patients with more extensive involvement, the outlook is far less promising.

CHANGES IN THE PERIPHERAL BLOOD

When desiccated defatted whole stomach or liver or liver extract is fed to patients with uncomplicated pernicious anemia, a characteristic "reticulocyte response" follows. This consists of (1) a latent period, (2) a rapid increase in the absolute number and percentage of reticulocytes, reaching a maximum, followed by (3) a decrease in the percentage until the pretreatment level or slightly above (1 to 3 per cent) is reached.

Maximum reticulocyte

$$\text{per cent} = \frac{0.73 - 0.2 E^{\circ}}{0.73 + 0.8 E^{\circ}}$$

(E° = Initial red blood cell count in millions
per cu mm)

The following table shows the calculated maximum reticulocyte percentage with relation to the initial red blood cell count.

TABLE II

Initial Red Blood Cell Count*	Range of Maximum Reticulocyte Percentage	Average Maximum Reticulocyte Percentage

*Millions per cubic millimeter

The average actual maximum reticulocyte per cent for the hundred patients treated by liver or stomach was 23.7. The calculated maximum for this group was 21.52 per cent. For the 50 patients treated with liver extract the actual maximum was 22.36 per cent, while the calculated maximum was 23.43 per cent. For the 50 patients treated with desiccated stomach, the observed maximum was 24.19 per cent, while the calculated maximum was 19.61 per cent.

Figure 2 shows the relationship between the observed maximum reticulocyte percentage and the initial red blood cell count compared to the calculated maximum percentage for the liver extract cases and for those treated with stomach. It is evident that the patients receiving Ventriculin made from an average of 225 grams of fresh stomach daily responded as well as, if not better than, those receiving the extract made from an average of 536 grams of fresh liver daily. If whole liver and whole stomach have the same degree of hemogenic activity, one-half of it must be lost in making the liver extract.

Of the 50 patients treated with liver extract, the average length of time required to reach the maximum reticulocyte percentage was 6.9 days, while the average for the stomach treated patients was 7.52 days, a difference of a little more than one-half day. This was exclusive of patients receiving massive doses. In view of the fact that the stomach treated patients reached, and in many cases exceeded, the calculated maximum reticulocyte percentage, the 0.62 day increase in

the anemia is severe. This disappears as the blood bilirubin approaches normal, which is in about two or three weeks. It is interesting to note that within a few days after the treatment is begun, the pads of the fingers and palms, the chin, the cheeks and the tip of the nose become flushed. This reaction must be a vasomotor phenomenon as the flushing occurs before there is a demonstrable increase in the red blood cell count. The creases in the palms of the hands remain pale, however, and do not become red until the blood count is between $2\frac{1}{2}$ and 3 million red blood cells per cubic millimeter.

CHANGES IN THE NERVOUS SYSTEM

A very large majority of patients with pernicious anemia have symptoms referable to the nervous system of which the most common is paresthesia of the hands and feet. This symptom may entirely disappear with stomach therapy, although it is not entirely controlled in all patients. There is a less favorable effect on the more serious neurological complications, such as loss of the sense of position of the limbs, impaired control of the sphincters of the bladder and rectum, and spastic paraplegia, although occasionally the improvement may be remarkable. In some instances, the neurological manifestations are held in abeyance, or, less commonly, there may be a distinct advance in the symptoms despite the fact that the anemia has been controlled. The latter situation has not been observed so far in patients who have been treated with desiccated stomach, but has been known to occur in those who have received sufficient liver ex-

tract to keep their blood at a normal level. From our present experience, however, it is not possible to say that desiccated stomach is superior to liver in treating the neurological complications. In general it may be concluded that improvement in the minor neurological symptoms frequently occurs, but in patients with more extensive involvement, the outlook is far less promising.

CHANGES IN THE PERIPHERAL BLOOD

When desiccated defatted whole stomach or liver or liver extract is fed to patients with uncomplicated pernicious anemia, a characteristic "reticulocyte response" follows. This consists of (1) a latent period, (2) a rapid increase in the absolute number and percentage of reticulocytes, reaching a maximum, followed by (3) a decrease in the percentage until the pretreatment level or slightly above (1 to 3 per cent) is reached.

CALCULATED MAXIMUM RETICULOCYTE PER CENT

A valuable feature in studying the potency of a preparation is the height to which the reticulocyte percentage increases after the therapy has been started. Based on the study of the average maximum rise reached in many patients, Minot, Cohn and their co-workers⁴ noted that there was a relationship between the maximum height of the reticulocyte count and the initial red blood cell count. The lower the red blood cell count on the day that the first dose of the medicine was given, the higher was the rise in the number of reticulocytes. Riddle's formula⁵ is as follows:

Maximum reticulocyte

$$\text{per cent} = \frac{0.73 - 0.2 E^{\circ}}{0.73 + 0.8 E^{\circ}}$$

(E° = Initial red blood cell count in millions per cu mm)

The following table shows the calculated maximum reticulocyte percentage with relation to the initial red blood cell count

TABLE II

Initial Red Blood Cell Count*	Range of Maximum Reticulocyte Percentage	Average Maximum Reticulocyte Percentage
0.4	55.7 - 69.1	61.9
0.5	50.4 - 61.9	55.7
0.6	45.7 - 55.7	50.4

*Millions per cubic millimeter

The average actual maximum reticulocyte per cent for the hundred patients treated by liver or stomach was 23.7. The calculated maximum for this group was 21.52 per cent. For the 50 patients treated with liver extract the actual maximum was 22.36 per cent, while the calculated maximum was 23.43 per cent. For the 50 patients treated with desiccated stomach, the observed maximum was 24.19 per cent, while the calculated maximum was 19.61 per cent.

Figure 2 shows the relationship between the observed maximum reticulocyte percentage and the initial red blood cell count compared to the calculated maximum percentage for the liver extract cases and for those treated with stomach. It is evident that the patients receiving Ventriculin made from an average of 225 grams of fresh stomach daily responded as well as, if not better than, those receiving the extract made from an average of 536 grams of fresh liver daily. If whole liver and whole stomach have the same degree of hemogenic activity, one-half of it must be lost in making the liver extract.

Of the 50 patients treated with liver extract, the average length of time required to reach the maximum reticulocyte percentage was 6.9 days, while the average for the stomach treated patients was 7.52 days, a difference of a little more than one-half day. This was exclusive of patients receiving massive doses. In view of the fact that the stomach treated patients reached, and in many cases exceeded, the calculated maximum reticulocyte percentage, the 0.62 day increase in

FIG 2 The relationship between the observed maximum reticulocyte percentage and the initial red blood cell count compared to the calculated maximum percentage for the liver extract cases and for those treated with stomach

length of time to reach the maximum must be interpreted not as deficient potency, but as evidence of a longer period required to utilize and absorb the stomach tissue. The liver extract is soluble in water, whereas the stomach tissue is not. Some of the active

substance produced by the stomach tissue may be generated after the dried material has been ingested. Two lines of evidence suggest that this may be a factor, although not the only one. First, in patients in whom there is retention of gastric contents, with slow absorp-

tion, the reticulocyte response is delayed or submaximal

1 Man (No 233076), age 67 years There was considerable retention of food in the stomach 15 hours after the evening meal Initial red blood cell count 1,010,000 per cu mm, hemoglobin 24 per cent (Sahli) The patient received 30 grams of an active preparation of desiccated stomach daily A maximum reticulocyte percentage of 13.5 was reached on the seventh day instead of the calculated 31.7 per cent The reticulocyte percentage returned to normal on the 11th day The red blood cell count reached 2,760,000 per cu mm in four weeks and 4,480,000 per cu mm in ten weeks

2 Man (No 243961), age 70 years Food from a meal 15 hours previously was found in the stomach on gastric analysis There was a history of similar findings during previous gastric examinations The initial red blood cell count was 2,610,000 per cu mm The patient was given 80 grams of desiccated stomach daily A maximum reticulocyte percentage of 6.8 was reached on the seventh day, although the calculated maximum percentage was 7.5 per cent, which should have been expected for less than one-half the dosage used In four weeks the red blood cell count rose to 3,280,000 per cu mm

The second phenomenon which suggests that some of the active substance may be generated after the stomach tissue is ingested, is the thermolabile character of the material as compared with the relatively more thermostabile nature of the material in liver or liver extract While the dried stomach may be exposed for hours to temperatures of around 82 degrees C, in an atmosphere of petroleum benzene, without great loss of potency, in the presence of moisture, in 30 minutes at 60 degrees practically all the hemogenic activity is destroyed It is possible to extract some of the active principle from fresh stomach⁴³ or from Ven-

triculo⁴⁴ with water An acid aqueous extract (pH 4.5), evaporated at 82 degrees C proved to be ineffective in three patients who subsequently responded well to whole desiccated stomach An extract made by a method similar to that used in preparing liver extract, except that some of the protein was precipitated by a lead solution, showed but the faintest trace of activity (observed reticulocyte response 5.6 per cent, calculated 24.3 per cent) in a patient who subsequently responded perfectly to whole desiccated stomach tissue It is possible that the material was inactivated when heated to the temperature of 60 degrees C Meulengracht, et al,⁶ were unable to extract the active principle from stomach, using the methods reported by Cohn⁷ in the preparation of liver extract In interpreting these experiments it must be remembered, however, that the active principle may be destroyed more easily in the environment of the normal hog stomach tissue constituents (e.g., hydrochloric acid and pepsin present) than in the liver tissue, or may be more thermolabile

The next group of experiments throws light on the problem from another angle It was desired to study the hemopoietic activity of the various constituents of the stomach, to note whether one part was more active than another It was known from clinical experience that muscle tissue (meat) alone was not active in inducing a remission in pernicious anemia Sharp⁸ had postulated the theory that stomach tissue would be an active hemogenic agent because it had arisen from the same embryonic layer as the liver, al-

though Castle's¹ work has suggested a specific secretion from the stomach as an activating agent.

The mucosa and muscularis layers were carefully separated, dried and fed separately to patients with pernicious anemia. It was found that either layer was very effective in inducing the blood changes associated with a remission if the material was not heated. Thus 300 grams of fresh muscle layer dried to 64 grams caused a reticulocyte rise of 20.3 per cent (calculated rise 17.1 per cent) in a patient whose initial red blood cell count was 1.79 million per cu. mm. However, 30 gram doses (representing 230 grams of fresh muscle layer) for 10 days failed to cause a remission when the muscle tissue was dried, defatted with acetone and exposed to a maximum temperature of 65 to 82 degrees C. in the process. Similarly 64 grams of desiccated mucosa (representing 360 grams of fresh tissue) not exposed to heat, caused a maximum rise in the reticulocytes of 41.8 per cent in a patient whose expected rise was to 25.0 per cent. This confirmed the work of Wilkinson¹⁵ and explained our inability to obtain similar results in our original experiments² as the importance of the temperature factor was not appreciated at the time the first experiments were performed. The glandular portion of the mucosa, desiccated at a temperature of 65 to 82 degrees but not defatted, was fed in 30 and 60 gram doses daily (representing 158 and 316 grams of fresh mucosa) to another patient whose initial red blood cell count was 1,230,000 per cu. mm. With 30 grams daily there was a reticulocyte response to 6.8 per cent instead of the

expected 27.5 per cent. With 60 grams there was a secondary rise to 9.3 per cent. Subsequently this patient received whole stomach (28 grams of desiccated stomach representing 240 grams of the fresh organ) and had a very satisfactory increase of the reticulocytes to 36.6 per cent, in comparison to a calculated rise of 20.0 per cent. In four other patients who were fed this heated mucosa, three gave no reticulocyte response at all and one gave a questionable slight response.

It is of importance to recognize, however, that when the muscle layer and mucosa are ground together, and then exposed to the temperature of 65 to 82 degrees C. in the drying process, the hemopoietic activity is not destroyed. It is thought that an enzyme-like material is formed in the mucosa, and that it acts rapidly on the muscle layer at the death of the animal, so that by the time the two layers can be separated, some of the active material has been generated or has diffused through the tissues. The work of Castle suggests that this "enzyme" or generating substance is absent in the stomachs of patients with pernicious anemia. His evidence is that it is excreted by the stomach, and the present work shows that it originates from the glands of the mucosa.

VARIATIONS IN RETICULOCYTES DURING SHORT INTERVALS

Porter and Irving²⁰ have reported that following the administration of a potent aqueous extract of liver to patients with pernicious anemia there is a variation in the percentage of reticulocytes in as short an interval as a few hours. A study of the blood of twelve

patients (six treated with liver extract and six with desiccated stomach) was made at two to four hourly intervals to obtain additional information concerning this. It was found that in both groups there was considerable variation in the absolute numbers and percentages of reticulocytes during the course of the day. Variations up to a 168 per cent increase in two hours have been noted after desiccated stomach therapy and a 21 per cent increase in four hours after massive doses of liver extract. There was a tendency for the reticulocyte counts to be higher in the afternoon and evening than at other times during the day, but the incidence of the highest counts for all patients fell more frequently (31) during the sleeping hours (8 00 P M to 4 00 A M inclusive) than during the day (8 00 A M to 4 00 P.M inclusive).

Several factors enter into the prolongation or shortening of the three periods. Chronic infection prolongs the latent period, decreases the maximum percentage of reticulocytes and prolongs the period required for the return of the reticulocyte percentage to normal. The following case histories illustrate this condition.

EFFECT OF INFECTION

A patient (Case No 240147) with pernicious anemia had septic tonsils and chronic bronchitis. His initial red blood cell count was 1,120,000 per cu mm, hemoglobin 15% (Sahli) and leucocyte count 4800 per cu mm. He did not develop a leucocytosis at any time. His temperature during the first 27 days ranged between 99° F, and 102.5° F (37.5° C to 39° C) but was normal after the 28th day. The reticulocyte count reached a maximum of only 27.4% instead of 31.7% on the 17th day instead of the 7th or 8th day, and did not return to normal until the

29th day. However, in 62 days his red blood cell count reached 6,280,000 per cu mm and his hemoglobin 74% (Sahli), after taking 40 to 50 grams of dried stomach daily during the first 4 weeks and 20 grams daily thereafter.

Another patient (Case No 235661) with pernicious anemia and acute otitis media, had a temperature ranging from 99° F to 102° F (37.5° C to 38.9° C) during the first 17 days of treatment. During this time the maximum rise of the reticulocytes in response to the daily feeding with 40 grams of dried stomach, was 11.3% instead of the calculated 45.7%. On the 9th day of therapy he was given a blood transfusion. Following this there was a subsidence of the fever and improvement physically. The dried stomach was continued, and the reticulocyte percentage fluctuated from 6.2 to 11.8%. However, on the 10th day it reached a maximum of 19.5%, which was the calculated maximum for the new post-transfusion level of the red blood cells. Subsequently his red blood cell count rose to 5,310,000 per cu mm and his hemoglobin to 88% while taking 20 grams of the dried stomach daily. This patient did not show a leucocytosis during his infection.

Infection may cause a fall in the red blood cell count in spite of adequate therapy. Acute infection may not only prevent the rise in the reticulocyte percentage, but when once begun may cause its rapid fall. In a patient receiving liver extract, who developed erysipelas, it was noted that there was a rapid decrease in the number of reticulocytes (inhibition of production) and a failure of the red blood cell count to increase. After the infection there was a rapid recovery in the erythropoietic function.

Another circumstance which prolongs the three periods, and which prevents a maximum reticulocyte rise to its proper degree, is found when the therapeutic preparation is weak or

FIG 3 Shows the effect of suboptimal doses of an experimental preparation of dried stomach of a potency lower than normal 15 grams produced a definite effect but it was lower than one would expect 20 grams increased the effect and the maximum response followed the increase to 30 grams daily.

when the dose is insufficient The following figures show this condition in a patient receiving a non-defatted preparation of stomach of low therapeutic efficiency (Figure 3) and one receiving

liver extract of low potency. (Figure 4)

Figure 3 shows the increasing reticulocyte response in a patient fed increasing, but suboptimal amounts, of

a special stomach preparation of low therapeutic value. Figure 4 shows the effects of two liver extracts of low therapeutic value, compared to the increase in the percentage of reticulocytes after a potent preparation.

A dose above the maximum may shorten the normal four to five day period, after therapy has begun (Figures 5 and 6).

Patient No 241545, age 30 years. The patient was given 50 grams of desiccated, defatted stomach on the first day, 150 grams the second day and 40 grams daily thereafter. The "reticulocyte response" began within 24 hours, and was well established in 48 hours. The maximum of 59.0% was reached on the 6th day (calculated maximum 45.7%) (Figure 5).

Patient No 194213, age 43 years. The

patient was given 30 vials of Lilly's Liver Extract by stomach tube. The "reticulocyte response" began within 48 hours, reaching a maximum of 55.7% on the 4th day (calculated maximum 45.7%) (Figure 6).

A submaximal reticulocyte rise due to a suboptimal dosage may be followed by a second reticulocyte rise if an optimal dose of an active preparation is given.

Patient No 241529, man, age 59 years. When first examined the patient had been taking 3 vials of Lilly's Liver Extract daily for 12 days. He had an excellent subjective response, and on the 15th day his reticulocyte count had fallen to normal. He was then given 30 grams of desiccated, defatted stomach daily. A second "reticulocyte response" developed, reaching a maximum of 11.9% (calculated 20.4%).

FIG 4 Shows the effect of three commercial liver extracts on a patient with pernicious anemia. The first produced a delayed and inadequate response in increasing the percentage of reticulocytes, slightly accentuated by the second, but not at all comparable to the effect from the third (No 343, N.N.R.)

FIG 5 Shows the rapid and marked increase in the percentage of reticulocytes after massive doses of dried stomach, given by a stomach tube, to an irrational patient with pernicious anemia. The response started within 24 hours, instead of three to five days, and reached a very high maximum.

Patient No 227706, man, age 59 years. The patient took 3 vials of Lilly's Liver Extract daily for 21 days. At the end of this time the reticulocyte count had fallen to 7.1%, and reached normal during the next 3 days. He was then given 30 grams of desiccated, defatted stomach, and had a second "reticulocyte response" to 14.1% (calculated 38.0%)

The secondary rises in the percentage of reticulocytes are always below the calculated, the first rise having cleared out some of the immature cells of the bone marrow

EFFECT OF BLOOD TRANSFUSION

Three patients received blood transfusions at the beginning of their dried stomach therapy, because of unusual weakness, impending infections, or exhaustion. In two of these the rise in the percentage of reticulocytes was nearer to the calculated maximum for the new, post-transfusion level of the erythrocyte number, rather than to the original pre-transfusion count. Table III)

FIG 6 Shows the rapid response when a massive dose of liver extract was fed to a patient with pernicious anemia. The reticulocyte increase began with 48 hours, instead of from three to five days.

TABLE III

Patient	Initial RBC Count Millions per cu mm	Expected Maximum Reticulocyte per cent	Post Transfusion RBC Count Millions per cu mm	Maximum Reticulocyte per cent.	
				Expected	Actual
241074	0.89	38.0	1.34	26.5	35.1
162296	0.69	45.7	1.21	29.0	33.5
235661	0.75	41.6	1.63	20.4	19.5

CHANGES IN THE RED BLOOD CELL COUNT

In a group of 46 of the 50 patients of whom complete data was available, the following chart shows the average increase in red blood cell count per week after adequate doses of desiccated stomach

400,000 per week. Individual patients reaching red blood cell counts of four million per cu mm or more showed increases of 994,000, 637,000 and 580,000 per week. The rate of increase was not equal during all months following the beginning of the treatment, being slower after the first month and

TABLE IV

Week	Number of Observations	Average Red Blood Cell Count Millions per cu mm	Week	Number of Observations	Average Red Blood Cell Count Millions per cu mm
0	46	1.72	7	10	4.14
1	45	1.73	8	18	4.34
2	39	2.34	9	6	4.60
3	23	2.57	10	4	4.40
4	13	3.26	11	4	4.82
5	20	3.34			
6	10	3.61			

It will be noted that during the first week of therapy there was practically no increase in the average number of red blood cells per cubic millimeter. In individual cases there was a slight increase and in others an actual decrease in number. The first significant rise is generally noted after two weeks. After the first week there is an average increase, for all the patients, of

comparatively very slow after the second month. Figure 7 shows the monthly changes for 46 patients, compared with those of 90 patients treated with liver diet, and reported by Minot and Murphy.⁹ The average rate of increase in the two is substantially the same, being slightly more rapid in the stomach treated cases than in this liver treated group.

RELATION OF SIZE OF DOSE AND RATE OF CELL DEVELOPMENT

There appears to be a definite correlation between the size of the dose of desiccated stomach and the time required for the red blood cell count to reach four million or more per cubic millimeter. Seven patients receiving from 100 to 199 grams per day (in terms of fresh tissue) required on the average 52.4 days to reach four million red blood cells per cu mm. Ten patients receiving 200 to 249 grams per day required 40.1 days to reach the same level (Figure 8). Of 25 patients with initial red blood cell counts of 0.9 to 2.8 million per cu mm, no patient with uncomplicated pernicious

anemia required more than 35 days to reach the four million level if he received more than the equivalent of 230 grams of fresh stomach, and no patient reached four million in 35 days unless he received 180 grams or more. Eleven patients in this group received from 186 to 215 grams of stomach (in terms of the fresh material) and required from 28 to 63 days to reach four million red blood cells per cu mm, regardless of the initial count. The following table shows a comparison of the average number of days to reach the four million level when liver extract or when desiccated stomach was used. This does not take into account the varying dosage.

FIG 7 Shows the average increase, by months, in the red blood cell counts of pernicious anemia patients treated with whole liver and with desiccated stomach. The upper line (stomach) shows a slightly more rapid rise when compared with the lower (liver), although the difference is probably not significant.

FIG 8 Shows the average increase in the rapidity of the improvement of the red blood cell count when larger doses of desiccated stomach are fed, in comparison to smaller doses

TABLE V

R.B.C (Millions)	Number Patients	Liver Extract	Number Patients	Dried Stomach
0-0.9	7	56.9 days	2	51.5 days
1.0-1.9	17	38.6 days	14	47.9 days
2.0-2.9	9	34.9 days	9	43.0 days

It is thus evident that within the dosage group classified as "adequate" it takes, on the average, comparatively longer for the patients with red blood cell counts below one million per cu mm. to reach normal, than for those having a higher initial count. In both the stomach and liver treated groups it required but four to five days longer, on the average, for the 1.0 to 1.9 group than the 2.0 to 2.9 group to reach the four million level.

WHITE BLOOD CELLS AND PLATELETS

With the onset of the remission, there is a gradual increase in the number of white blood cells and platelets¹⁸. There appears to be no gross difference between the response after liver extract and after stomach therapy. Eosinophilia has been reported after raw liver diet, but no definite eosinophile increase has appeared after desiccated stomach therapy in the blood of 30 patients examined daily during the first 30 days, and at intervals during six to twelve months afterwards¹⁹.

RATE OF UTILIZATION, EXCRETION OR DESTRUCTION: RELAPSES

Riddle and Sturgis¹⁰ showed that 30 vials of liver extract given in one dose had the same effect as three vials of

liver extract given daily for ten days Kandel²¹ also reported a case in which 240 grams of Ventriculin given in four days were effective for eleven days. The material is evidently stored in the body, and not excreted or destroyed at once. It is suggestive that when the material is made by gastric digestion in a normal person, it is stored, possibly in the liver, as this organ appears to have such a rich content of the material. The storage of the active material may be the mechanism by which a remission is maintained after the cessation of stomach or liver therapy. The length of a remission, when therapy is discontinued, varies with each patient. The relapse is apparently more rapid when no medication is taken than when a subminimal dose is used. Of 35 relapses in 33 patients which relapsed because of discontinuance of therapy, or too small dosage or non-potent material, records are on hand of three patients on stomach therapy and 32 on liver or liver extract therapy. The relapses, as indicated by a decrease in the red blood cell count, appeared in from ten days to nine months. The average period for the development of a complete blood relapse is probably slightly less than two months, and appears to be essentially the same in patients treated with liver extract or with stomach, although the series is at present too small to permit the drawing of definite conclusions. In the three relapses in patients treated with stomach, the blood count decrease was noted in from two to two and one-half months after a normal blood count, during which period the medication had been discontinued or an insufficient amount taken. The most rapid relapse after

liver extract therapy was noted in a patient in whom the red blood cell count fell from 5,060,000 per cu mm to 2,300,000 in ten days. There is evidently rapid destruction or counteraction of the hemopoietic substance during infection.

PATIENTS APPARENTLY REFRACTORY TO LIVER, RESPONDING TO DRIED STOMACH

Occasionally a patient is encountered who does not respond perfectly to liver, and the blood count cannot be increased appreciably above three million per cubic millimeter. The following case history illustrates this point.

A man (Case No 210673), age 65 years, gave a history of pernicious anemia of at least 3 years duration. When liver extract, 6 vials daily, (343, NNR) was begun his red blood cell count was 1,250,000 per cu mm, and his hemoglobin 25% (Sahl). He had a typical "reticulocyte response" and in 23 days his red blood cell count was 3,400,000 per cu mm and his hemoglobin 65% (Sahl). He was given 4 vials of a liver extract daily after this, but no change was noted in the blood count in 36 days. It was thought that the particular liver extract used was not of normal potency, so the dose was doubled (8 vials daily). No change occurred in 21 days and the liver extract was changed to a lot of known potency, 4 vials (343, NNR) daily. There was a slight drop in the red blood cell count in 30 days, it was unchanged in 35 more days of this therapy, and again the same after 34 more days, and 26 days and 63 days. Thus the blood count remained around 3 million for 245 days using what was usually an adequate dose of a potent liver extract. The patient was then given 14 grams of dried, defatted stomach daily, the dose being reduced to 10 grams later. The blood count taken 8 weeks later showed a slight increase to 3,870,000 red blood cells per cu mm., and 83% hemoglobin (Sahl), with great subjective improvement. The count rose

rapidly to 4,390,000 per cu mm and the hemoglobin to 91% (Sahli) where it has remained for 3½ months to the present

Renshaw,¹¹ Leschke,²⁸ and Snapper and Dupreez¹² reported similar cases.

EFFECT OF LIVER EXTRACT, LIVER OR DESICCATED STOMACH ON SECONDARY ANEMIAS

Sixteen patients with various types of anemia were treated with liver or liver extract and three with desiccated stomach. In only two was there a therapeutic response attributable to the medication. One, a patient with fish tape worm infestation and anemia, responded well to whole liver and the other, a patient with myxedema and anemia, responded to liver extract. While either liver or stomach therapy appears to be specific for the macrocytic anemias of the pernicious anemia type, including sprue (Castellani,¹⁸) it is possible that empirically other conditions may be found which may be helped.

CAUSES OF FAILURE IN THE TREATMENT OF PERNICIOUS ANEMIA WITH DESICCATED STOMACH OR LIVER EXTRACT

Our experience seems to have demonstrated clearly that the blood of a patient with uncomplicated pernicious anemia will return to normal following the administration of adequate doses of desiccated hog's stomach^{2, 3}. Proof of this is to be found in treating our own series of 100 patients and confirmatory evidence is available in the published results of Conner,¹⁴ Wilkinson,¹⁵ Renshaw,¹¹ Snapper and Dupreez,¹² Rose-nov,¹⁶ Meulengracht and Hecht-Johansen,⁶ Hitzengerber¹⁷ and others²¹⁻⁴⁷.

When the treatment is applied to some patients, however, the anticipated improvement may not follow. This situation requires the careful consideration of several possible explanations as follows:

1 The diagnosis of pernicious anemia may be incorrect. As far as it is known at present, desiccated stomach is effective only in pernicious anemia and sprue.¹⁸ Assuming that it has an action similar to liver or liver extract, it may be surmised that it will also benefit patients with the so-called "pernicious anemia" of pregnancy, and the anemia associated with *Dibothryocephalus latus* infestation. There are other varieties of anemia which resemble the pernicious type and yet do not respond to stomach therapy. Probably one of the most confusing is aleukemic leukemia, which in some instances is differentiated from pernicious anemia only with the greatest difficulty. All other types of anemia which do not respond to the modern treatment of pernicious anemia must be eliminated before it can be said that the therapy is ineffective.

2 It is known that any type of acute infection with a febrile reaction reduces, to a certain extent, the effectiveness of desiccated stomach. If the treatment fails, therefore, an attempt should be made to eradicate all forms of active infection. If this cannot be eliminated, the dose should be doubled and every effort made to minimize the effect of the counteracting agent.

3 Occasionally failure is due to the fact that the patient is not under constant observation and takes only a small portion of the prescribed dose. Too often efficient therapy is discarded be-

cause the red blood cell count is said not to increase during the first week or two of treatment. While it is true that the average red blood cell count increases between 400,000 and 500,000 per cu mm per week, this increase is not always in the form of a smooth curve for each patient. As shown in an earlier section, in some there is no change for a week or two, and then a rapid rise at the rate of a million or more cells per cu mm per week. It should be emphasized, furthermore, that the earliest change which is noted in the blood is not necessarily a rise in the red blood cell count but an increase in the reticulocytes. It should also be emphasized that the number of reticulocytes which appear following treatment is inversely proportional to the initial red blood cell count before treatment, and that they do not show as an increased percentage in the peripheral blood when the red blood cell count is three million or more.

4 If the above possible explanations can be eliminated, it must be concluded that the preparation used is not potent. This possibility may be eliminated if the preparation which has been used is known to have been subjected to a clinical test by responsible observers and certified as active. The preparation of defatted, desiccated hog stomach is not a complicated procedure, and the possibility of destroying the potency of the material during the manufacturing process should not be great. But, as the active material in the substance is not identified, its exact stability to heat and various changes of pH are not known, and very slight alterations in these may readily impair

or completely destroy the potency of the preparation.

PRACTICAL MANAGEMENT OF PATIENTS WITH PERNICIOUS ANEMIA

The essential part of the treatment is to be assured that the patient receives a sufficient amount of potent material which is effective in the treatment of pernicious anemia. If desiccated stomach (Ventriculin) is used, a safe daily dosage is ten grams for each million deficit in the red blood cell count. For example, if the red blood cell count is one million, there is a deficit of four million, and the dosage should be 40 grams daily, when the level of the red blood cell reaches two million, the deficit is three million, and the dosage should be 30 grams daily. After the blood becomes normal it is necessary for the patient to continue with a maintenance dose for an indefinite period in order to prevent a relapse, which will occur at a variable period after the medication is discontinued. The precise dosage per week which is necessary to prevent a recurrence of the anemia is not definitely known at present, and it is possible that it varies with different patients. An average dosage is ten grams a day for five or six days a week. When the dosage has been reduced to ten grams daily, the only safe plan is to have the patient report at intervals of every two or three weeks for a blood examination. If the red blood cell count remains at a normal level for over two months, it may be concluded that the dosage is adequate, but if there is a decrease, a larger dosage is indicated. From our experience we have con-

cluded that the most accurate single criterion of the adequacy of the dosage is the level of the red blood cells, and this should be determined at each time the patient returns for examination. Although the red blood cell count may increase to more than five million per cu mm, there is no evidence that it will reach an abnormally high level if an excess of medication is given. The fear, therefore, that a polycythemia may develop is unwarranted.

The accessory methods of treatment depend upon the symptoms. A patient with anemia should remain at rest in bed for the first week or two of the treatment if the red blood cell count is extremely low. It has been our practice, however, to urge patients to become ambulatory at the earliest possible moment but to avoid excessive fatigue. The diet should be liberal and well balanced, but otherwise requires no special attention. With a few exceptions, the choice of food may be left to the patient as the increased appetite which develops with the treatment usually calls for a wide variety of food in large amounts. There is no convincing evidence that it is necessary to administer dilute hydrochloric acid, despite the fact that patients with pernicious anemia have an achlorhydria and free hydrochloric acid never returns in the gastric contents after the blood becomes normal. In the series of patients whom we have treated about one-half were given dilute hydrochloric acid in doses of 4 c.c., *t i d*, or more, and the others received no medication except liver, liver extract or desiccated stomach. The results in both groups were equally good and there was no apparent difference in the rate of re-

covery from the anemia or the rapidity with which the gastro-intestinal symptoms disappeared. As the effect of the modern method of treatment is so prompt and satisfactory, it does not seem necessary to employ the therapeutic agents such as iron and arsenic, and they have not been used in the patients whom we have observed.

For the prevention of bed sores, reddened areas may be coated at frequent intervals with a collodion solution. When the bed sores are large, necrotic tissue may be cut away and wet dressings of boric acid can be applied. When the edges become clean, the wound may be exposed to the air, or to the light and heat from an ordinary carbon filament electric light bulb.

IMPORTANCE OF COMPLICATING INFECTIONS

As previously emphasized, an acute infection of any type, if it is associated with fever, causes the action of liver or desiccated stomach to be less effective. The infection which is most frequently encountered is one involving the urinary tract, and usually consists of a cystitis alone or a cystitis associated with a pyelitis. This arises in patients with spinal cord changes, which result in urinary retention due to loss of control of the sphincter of the urinary bladder. Any other type of infection, such as acute tonsillitis, sinusitis, bronchitis, bronchopneumonia, acute cholecystitis, or erysipelas may produce the same deleterious effect. It is doubtful if various foci, such as chronic and mild infection about the teeth, are of importance in this connection, and, therefore, their removal

should be recommended only after it has been demonstrated conclusively that efficient stomach therapy is not producing satisfactory results. In the presence of an acute complicating infection with fever, every method to combat it should be employed, and in addition the dose of desiccated stomach should be increased from 50 to 100 per cent.

BLOOD TRANSFUSION

It is rarely necessary to resort to this procedure as most patients react promptly to liver or stomach therapy. It is useful, however, as an emergency measure, and should always be considered when the patient's condition is serious or if red blood cell count is one million per cu mm or less. It has been our practice to determine the blood group of all patients whose red blood cell count is one million or less, and to have a donor available for use if it appears that the patient may die before the usual therapy has time to act. Some patients with an extremely low red blood cell count are delirious and uncooperative when first seen, which makes impossible the administration of any medication by mouth. As there is no effective preparation of liver or stomach, commercially available which can be administered subcutaneously or intravenously, and the injection per rectum is only moderately efficient, the medication must be given by means of a stomach tube. Excellent results may be obtained by employing a tube with semi-rigid walls and administering 100 grams or more of desiccated stomach which has been mixed with a sufficient quantity of water to insure that it will pass through the tube readily. Al-

though a portion of this may be vomited, a sufficient quantity will be retained to produce an effect, and more may be given at intervals of three or four hours.

DISCUSSION

The fact that desiccated, defatted, hog's stomach is effective in the treatment of pernicious anemia is of importance from a practical as well as a theoretical standpoint. There is no evidence that this preparation is more effective than liver in the treatment of this disease, although our observations are compatible with the conclusion that fresh stomach tissue contains, or develops, the active substance in a more concentrated form than fresh liver. It is possible, however, that this is not the case, as a fairly large amount of the active principle in liver may be destroyed or lost in the process of manufacture of liver extract. As the preparation of desiccated stomach is relatively simple and the original tissue employed is ordinarily regarded as a waste material, the cost of the finished product should be less than liver extract. When it is considered that a patient with pernicious anemia must consume a certain amount of effective material constantly in order to maintain health, this is an important item for consideration. Most of the patients do not find the material difficult to consume, and some prefer it to liver extract. At present liver extract has the advantage of being soluble in water, whereas the desiccated stomach does not dissolve.

Certain theoretical considerations as to the nature of the development and method of action of the blood-maturing substance offer opportunity for

speculation. The blood-maturing substance appears to be present in liver tissue as a definite material and it can be extracted and concentrated. The potency of the whole stomach suggests, then, that the material is developed post mortem in the tissues. A generating substance, then, may exist in one layer (the mucosa) which acts on the proteins of the other layer (muscularis). It is possible that the generating substance is of the nature of an enzyme, and it is apparently excreted in normal gastric juice. The fact that the material can be made in the stomach during gastric digestion, and is present in liver and other tissues, leads one to conclude that it may be made and stored by the body. This probably accounts for the latent period of development of anemia when liver or desiccated stomach tissue therapy is discontinued. The desiccated stomach may have a supply of the active substance which it has generated while drying, or additional substance may be made after it has been ingested. Meulengracht and Hecht-Johansen⁶ suggest that this is the case, as they were unable to extract it by the method of Cohn used in making liver extract. However, it may be that the material is destroyed by this process, although it hardly seems possible that it should be stable in liver tissue and not in stomach tissue.

The fate of the substance is not known. The quantitative relationship between the size of the dose and the rate of response, and the relapse when the dose is below a certain minimum, suggests that a certain definite amount of the material is used. More of the active substance is required and used

when the peripheral blood count is low than when it is high. Three vials of Lilly's Liver Extract or ten grams of desiccated stomach (Ventriculin) daily, supply sufficient material when the red blood cell count is four and one-half to five million per cu. mm, but the response is very slow if this dosage is given when the cells number one million or less per cu. mm.

There are several possible ways in which the active material may act:

1. *Replacement Theory*. The active material may supply a missing substance directly and cause a normal development of the blood.

2. *Hormone Theory*: It may stimulate other organs, or tissues, to produce an adequate amount of a hemogenic substance, or change the rate of growth of the bone marrow cells directly.

3. *Defective Metabolism Theory*. It may act as an intermediate substance which, after undergoing further metabolic changes, becomes part of the developing red blood cells.

4. *Antitoxin Theory*. The material may neutralize an inhibiting substance.

The lessened activity of the active substance as the blood count approaches normal, as evidenced by the decreased production of reticulocytes and the slower rate of increase of the red blood cell count during the later weeks and months after the beginning of therapy, suggests that the material has a specific action on the stages of the red blood cell which are most numerous during the relapse, the megaloblast and normoblast. It is possible that the increase in the number of white blood cells with the onset of the remission is a mechanical incident, associated with the release of large num-

bers of cells from the crowded, hyperplastic bone marrow. This is somewhat substantiated by the absence of improvement in the leukemias after liver extract or desiccated stomach therapy.

SUMMARY AND CONCLUSIONS

1 Defatted, chopped, desiccated whole stomach (hog) is effective in inducing and maintaining a hemopoietic remission in pernicious anemia.

2 A comparison has been made in the clinical progress and laboratory data of 50 patients treated with Lilly's Liver Extract (No 343, N N R) and 50 patients treated with desiccated, defatted stomach (Ventriculin, N N R).

3 The defective maturation of immature red blood cells in the bone marrow of patients with pernicious anemia appears to be related to the lack of an enzyme-like substance developed in the gastric mucosa.

4 The material made by the mucosa, produces from protein a substance which stimulates red blood cell maturation.

5 The material may be produced post-mortem when the mucosa and muscle layer are ground together.

6 The subjective and objective changes in both groups (liver treated and stomach treated) are alike.

7 As with liver extract, the maximum reticulocyte count is inversely proportional to the initial red blood cell count, after desiccated stomach therapy. The anticipated maximum reticulocyte count may be estimated with a remarkable degree of accuracy.

8 The reticulocyte count may vary during the course of the day from one

or two per cent to 16.8 or 21.0 per cent, in two to four hour intervals. The greatest increase in the reticulocyte percentage came most frequently during the hours of sleep at night, in the cases studied.

9 The response to the therapy may be lessened or inhibited in the presence of infection or if the preparation is weak or the dose insufficient.

10. The latent period before the development of the reticulocyte increase may be shortened by a massive dose of liver extract or desiccated stomach.

11. A submaximal reticulocyte rise, due to a suboptimal dosage, may be followed by a second reticulocyte rise if an optimal dose of a second preparation is given.

12 The reticulocyte response may be submaximal in patients who have gastric retention.

13 A decrease in the maximum reticulocyte percentage following desiccated stomach therapy has been noted after blood transfusion.

14. The average length of time for 50 patients treated with Ventriculin to reach the maximum reticulocyte percentage was 7.52 days, whereas for the liver group it was 6.9 days. The difference is attributed to the greater solubility of the liver extract, with more rapid absorption.

15 The average maximum reticulocyte percentage of the liver treated group was 22.36 per cent (calculated 23.43 per cent) while that for the stomach treated group was 24.19 per cent (calculated 19.61 per cent).

16 During the first week or two of therapy the increase in the number of

red blood cells may be negligible, but after that there is an average increase of about 400,000 per week, more rapid during the early weeks and slower as the five million level is reached

17 Within the limits of adequate dosage, the larger the dose of desiccated stomach, the shorter the time required to reach a normal red blood cell count.

18 With the development of the remission, the number of leucocytes and blood platelets approaches normal.

19 No eosinophilia has been noted after stomach therapy, as after raw liver therapy

20 The active material in liver extract or desiccated stomach may be stored in the body, the supply or effect being adequate for a variable pe-

riod, but is rapidly counteracted or neutralized by infection.

21 Causes of failure of liver extract or desiccated stomach therapy are incorrect diagnosis, infection, insufficient dosage, or deficient potency of the preparation

22. The optimal daily dosage of desiccated stomach is ten grams (equivalent to about 67 to 70 grams of fresh stomach) for each one million deficit in the red blood cell count.

23. Active infection must be eliminated and in its presence the dose of desiccated stomach or liver extract must be increased.

24. Blood transfusion may be indicated in selected cases with extremely low blood counts, debility or acute infection.

The Adequate Treatment of Anemia*†

By GEORGE R. MINOT, M.D., S.D., F.A.C.P.,** and WILLIAM B. CASTLE, M.D., F.A.C.P.,*** *Boston, Massachusetts*

INTRODUCTION

THE adequate treatment of anemia necessitates removal of the causes, whether proximate or remote, with attention to all aspects of a given case. The dependence to a greater or less degree of many cases of anemia upon an inadequate nutrition of the individual either produced directly by defects of the diet, or indirectly conditioned by a defect of the individual, makes the study of this aspect of the problem of primary importance. For this reason, it is our object not to discuss the use of special procedures such as transfusion of blood or splenectomy, but to emphasize the importance of a suitable diet and the use of optimal quantities of certain

potent substances contained in food and shown to work almost as specifics for certain types of anemia. Adequate treatment, however, implies that the individual peculiarities of each patient and of his condition must be considered.

PERNICIOUS ANEMIA

The adequate treatment of pernicious anemia is accomplished not by liver, kidney, stomach, brain, or potent preparations obtained from these organs, but by *enough* potent material, irrespective of the source, for the given individual throughout life. Successful treatment demands that the physician should know that the patient actually takes the amount prescribed. Sometimes the patient believes that he has been taking the proper amount, but after the physician inquires carefully, he discovers that the individual frequently omits a dose or has undoubtedly taken an insufficient amount. Confusion can arise from the fact that the amount of liver purchased will not be the amount of liver ingested. The amount prescribed should be the quantity to be swallowed. In preparing raw liver pulp or cooking liver, frequently from 20 to 35 per cent of the tissue is lost. Doctors and patients often believe that if

the patient takes extract derived from 100 grams of an organ, he will obtain as much potent material as if he ingested 100 grams of the organ itself. Such is certainly not the case. Often the amount of extract derived from 100 grams of liver will be about as potent as 65 grams of prepared liver. The physician should know the potency of the preparation advised. He may obtain for himself such information by observations on the course taken by the reticulocytes or by referring to critical studies published by other persons. It is usually a relatively simple matter to initiate a remission in pernicious anemia by the daily feeding of various substances such as 200 to 300 grams of prepared liver or kidney, active extracts derived from 300 to 600 grams of liver, 150 or 240 grams of fresh whole pig stomach, or stomach mucosa or dried and defatted stomach prepared from this amount. Brain (Ungley) is about one-third as potent as liver. Failures will be found to be due to inadequate dosage, incorrect diagnosis or complications. Occasionally, unusually large doses are necessary, particularly because of complications and also sometimes owing to difficulty with absorption. When no response or a poor response has occurred with a known potent preparation, the amount should at least be doubled. In the case of a very sick patient, the entire dose of potent material for a week may be given within a few hours or even administered at one time to an unconscious patient by stomach tube. In this way the appearance of the response will be hastened.

Sometimes it is necessary to consider administering a potent preparation parenterally. Occasionally this method may be live-saving or be more convenient, and, under certain circumstances, it may have distinct advantages.[†]

The dose of potent material necessary for the maintenance of a normal red blood cell count and hemoglobin level and for the relief or prevention of progress of symptoms varies widely; in terms of liver extract* daily from that amount derived from 200 grams to that derived from 1200 grams of liver. The red blood cell count and hemoglobin alone should not determine the dose. These factors, considered together with the color index, the detailed character of the red cells (their size, volume index, etc.,) and white blood cells and blood platelets, and particularly the patient's signs and symptoms, should determine whether more, or rarely less, potent material should be taken. The object should be to make all aspects of the patient's blood normal and the patient himself as well as possible. The size of the cells can be fully as important a guide to dosage as the red blood cell count, but the patient's symptoms, especially if referable to the central nervous system, are as important as any laboratory examination in considering the amount of liver or potent substitute the individual should take. If a simi-

*Liver extract No. 343 Lilly (N. N. R.)

lar group of patients are compared, who have been relieved of severe anemia and who have had no definite subsequent relapse, (a condition always attributable to an *insufficient* amount of active principle or to complications,) it will be found that the patients who maintain the best health are usually the ones who take daily distinctly large amounts of potent material. It is important to adhere to the principle of supplying optimal quantities of effective substances to maintain the 'best possible' health rather than to supply only enough to maintain definite improvement. The prescription of a proper amount of potent substance demands a knowledge of conditions that may inhibit its action. Infections, disorders of the liver, kidney, and other organs can hinder the effects of liver and potent substitutes. The usual adequate dose may need to be increased because of age or arteriosclerosis. In fact, for old people with arteriosclerosis, it usually will require at least double the amount of active principle to maintain health that is needed for individuals without complications below the age of 45 years. An increased amount of potent material is indicated when neurological symptoms cease to lessen and of course when neurological complications tend to show further progress. Many patients under liver treatment have had lesions referable to the neuro-muscular system develop or increase because they did not take enough potent material for their individual needs.

The treatment of the lesions of the nervous system seems best carried out by feeding with regularity large

amounts of potent material—not merely the amount that will maintain a normal blood level. Whether the effect on the blood and the nervous system is due to one or more substances is open to speculation. Organs contain many substances not in extracts used for therapy and the latter in turn contain various materials, such as vitamin B₂ (G) in concentration, besides the substance crystallized by West and his associates, which is potent for blood regeneration in pernicious anemia. Possibly neuro-muscular symptoms may be affected more favorably by the feeding of organs than by extracts of equivalent potency for blood regeneration. Neuro-muscular symptoms often do not significantly change until the red blood cells have reached normal numbers and then may lessen very slowly. Since there is almost always some decrease in neurological symptoms with persistent large doses, the necessity of persevering with maximal amounts of active material is clear. If arteriosclerosis or complications are not present and especially if the nervous system lesions are of relatively recent origin or referable to the peripheral nerves, large amounts of liver or potent substitute will usually cause relatively rapidly pronounced improvement in the nervous manifestations. One can not expect, with long-standing advanced lesions of the central nervous system, great improvement in older people, but even in such cases, very large amounts of potent material over a prolonged period of time can be distinctly beneficial.

In carrying out adequate treatment, all aspects of the patient and his case

must be prescribed for. Care should be taken of the gastrointestinal tract and every effort made to obtain complete absorption of potent products. Appropriate, skillfully applied mechano-therapeutic procedures, mental hygiene, and many other sorts of matters must be wisely attended to. Certain restrictions often must be prescribed. One that has not been mentioned in the literature but which has been noted by Dr West of New York, as well as by Dr Murphy and ourselves, is that perhaps it is unwise for these patients to expose themselves to the sun sufficiently to tan their bodies intensively. Under such conditions it is possible that neurological manifestations have been distinctly aggravated and caused to progress with great rapidity.

Lack of attention to the diet may be a cause for a patient with pernicious anemia not to improve as much as possible. At times undesirable low color indices may occur when the red blood cell count is normal. Occasionally this state of affairs can be attributed to diets which for a long period of time have been scant in protein, vegetables and fruit. Under such conditions when the patient is taking ample extract of liver, the addition of iron may cause the hemoglobin to rise. The prescription of a proper diet is also obviously desirable. Sometimes, when the red blood cell count is about 4,000,000 per cu mm. and hemoglobin about 70 per cent, both the red blood cell count and the hemoglobin can not be increased by large doses of potent substances effective in pernicious anemia. In some such cases, especially if pronounced arteriosclerosis or obvious

complications are not present, iron in sufficient dosage will cause a distinct improvement not only in the blood but in the patient's sense of well-being.

If chronic blood loss is sufficient to cause anemia in a patient with pernicious anemia who has maintained a normal blood level with an adequate amount of potent material, he may develop hypochromic anemia which can be readily lessened by iron therapy*.

Other substances than iron, as well as food, may operate to improve the blood of pernicious anemia patients when they are in a state of remission. For example in rare instances hypothyroidism and pernicious anemia may be present in the same individual. The relief of anemia may not be completely possible without the administration of a potent thyroid preparation in addition to adequate therapy for pernicious anemia.

Frequently, after the patient appears to have improved as much as possible as a result of taking for months, not weeks, distinctly large quantities of potent material, the physician is confronted with this question which the patient more often asks before a month has passed by, "How much less medicine can I now take?" The answer is always difficult. It is safe, when the amount has been distinctly large, to curtail the dose somewhat. One should be prepared to return to large doses again on relatively slight provocations. It is unwise, however, for any patient with pernicious anemia to

*A chart illustrating this state of affairs for one of our cases is given in an article by R. T. Beebe and G. E. Lewis in the *Am. Jr. Med. Sci.*, 1931; clxxxi (June), 796.

take daily less than 200 grams of prepared liver or the amount of potent material equivalent to that contained in the most potent commercial extracts derived from 300 grams of liver.

An occasional patient with pernicious anemia may remain, as before the days of liver therapy, in a state of splendid remission without any particular treatment for a year and even more, but this in no way contraindicates the important principle for the patient with pernicious anemia to understand—namely, the necessity of continuing to take indefinitely and with regularity the quantity of potent material optimal for the given case.

Rarely cases with a blood picture of pernicious anemia occur with normal amounts of free hydrochloric acid in the gastric contents. Some such cases have arisen as the result of partial removal of the stomach or disorders of the lower intestinal tract, and some are cases of sprue. The principles of treatment are no different under these circumstances, just as it is unnecessary to administer hydrochloric acid to the case of pernicious anemia with gastric achlorhydria. This is because Castle has shown that individuals may have a normal gastric acidity yet lack the factor which is absent from the stomach in all pernicious anemia patients, who almost always have achlorhydria. This factor, which occurs in the normal stomach, when brought in contact with beefsteak, liberates a substance that is effective in pernicious anemia. It is likewise pointed out here that achlorhydria often occurs in patients

with idiopathic hypochromic anemia, but their gastric secretions contain the gastric factor lacking in pernicious anemia. One should recognize that it is not achlorhydria that conditions the state of pernicious anemia, but the lack of a particular factor secreted by the normal stomach which is not hydrochloric acid, pepsin, rennin, or lipase.

ANEMIAS THAT RESPOND TO IRON

The principles of the adequate treatment of anemias that can respond to iron are essentially the same as those set forth for pernicious anemia. Iron may have pronounced favorable effects on blood regeneration. The many conflicting statements in the literature concerning the value of iron therapy are probably dependent upon deductions from circumstances that were not the same. Iron may control important activities within cells, it influences growth and thus affects the body metabolism besides supplying this element for hemoglobin formation. The course taken by the reticulocytes will foretell, if properly evaluated, the effectiveness of iron therapy in a given case. The character of the curve for the reticulocytes in response to iron is somewhat different from that which appears with liver therapy in pernicious anemia. Likewise data concerning the reticulocyte increase from iron administration must be interpreted slightly differently than those for pernicious anemia.

There are various sorts of so-called "secondary" anemias that can be promptly alleviated by the use of iron in suitable doses. Anemia due to

chronic blood loss usually lessens rapidly under iron therapy. Patients with "secondary" anemia dependent upon either no well-recognized cause or associated with certain dietary deficiencies or altered gastrointestinal function, or both, are among those benefited often by iron. Such cases are common in women and the anemia may be enhanced by blood loss, pregnancy, infection, and other complications. The condition known as chronic chlorosis or hypochromic achlorhydric anemia is distinctly one in which the patient is favorably affected by large doses of iron. The rôle played by the disturbed gastric function is unknown but, indeed, may be most important.

Infections and various complications or conditions inhibit the action of iron comparable to the effect of such disorders on the treatment of pernicious anemia, so that brilliant results from iron therapy can not be expected in anemia of infectious origin. Likewise iron cannot influence aplastic or myelophthisic bone marrows or be definitely effective when a distinct degree of abnormal blood destruction continues to be operative as in chronic hemolytic jaundice.

The principle of giving enough iron to accomplish the best possible result must be adhered to. Often small doses of iron (75 mgs.) in the form of an iron salt such as ferrous carbonate, iron citrate, or iron and ammonium citrate or reduced iron may cause a rise of reticulocytes and slow improvement of the patient, when larger doses (0.5 gram) will produce brilliant and rapid results. Sometimes, especially in chronic chlorosis, a daily

dose of 75 mgs. of iron *per se* contained in a salt will produce no effect whatsoever, when 350 mgs. of iron will cause pronounced benefit. Although iron is apparently more effective when absorbed from an acid than from an alkaline medium in the upper gastrointestinal tract, if sufficient iron is given the ultimate benefit observed will be the same. Many papers have appeared concerning whether one sort of iron preparation is more effective than another. Although much more knowledge concerning this subject and the physiology of iron metabolism is desirable, it would seem that the form in which iron is prescribed is less important than that it is in sufficiently large quantities and in such a state that it can be readily absorbed. For this reason it would seem wise to give a salt of iron preferably already dissolved. Metallic iron may need solution by the body and pills or capsules containing iron compounds may pass through the gastrointestinal tract intact. Iron and ammonium citrate is a readily soluble inexpensive salt which may be given dissolved in milk. Because of the occasional diarrhea, induced by the large doses necessary, it is well to begin with a dose of about half a gram three times a day and increase to the generally useful dosage of two grams three times a day.

It is probably unwise to stop iron therapy as soon as the blood has returned to normal in a case that can be considered truly curable as, for instance, a case of chronic blood loss with the blood loss stopped. Presumably at the time the number of red blood cells and hemoglobin have

reached normal, the body is still deficient in iron, so that it is desirable for the patient to continue taking iron for at least some weeks after the blood appears to be completely regenerated. Moreover, there are undoubtedly cases of chronic chlorosis and somewhat similar cases with relatively higher color indices, in which the cause of the anemia is not clear-cut, that will inevitably relapse unless iron therapy is continued indefinitely. It is such cases that may have a defect in the utilization of iron, dependent in some way on abnormal gastrointestinal function comparable perhaps to the defect in gastric secretion that occurs in pernicious anemia. Adequate treatment of this type of patient demands frequent observations and the insistence of iron therapy presumably throughout the life of the patient. Omission of iron may cause relapse in from a few weeks to months or sometimes not for several years. Some data at hand suggest that after iron is omitted a relapse will occur sooner in the patients who have taken iron for a short rather than a long period of time.

Although iron alone can be very effective, there are other factors that can accelerate blood formation in anemias influenced by iron. Copper, under certain circumstances, probably especially in infants, as Josephs has shown, may enhance the blood-regenerating power of iron. Hart and his associates first demonstrated this effect in young rats with anemia produced by the feeding of a whole milk diet. The iron salts commonly prescribed for patients usually have copper in small amounts mixed with them and perhaps some of the effects cred-

ited to large doses of iron should be attributed to the synergetic action of copper and iron.

Liver contains many substances other than the active principle effective in pernicious anemia. The commercial extracts prepared particularly to supply the latter substance are effective in certain other megaloblastic anemias resembling typical Addisonian pernicious anemia. They are occasionally effective in severe anemias not suspected to be associated with a megaloblastic bone marrow. Usually these extracts are not significantly effective in "secondary" anemia and undoubtedly many patients have wasted money and effort in buying and taking such products that can not be expected to benefit them. Whole liver, in the large amounts effective for pernicious anemia, may have a remedial effect in many cases that can be benefited with iron. This effect is certainly not attributable only to the iron contained in liver. Whipple and his associates have shown that liver contains, in addition to iron, material effective in the promotion of hemoglobin regeneration in anemia due to chronic blood loss in dogs. They have isolated a fraction of liver potent in this respect that is distinct from the fraction effective for pernicious anemia. In their animals, supplementing this liver fraction with small amounts of whole liver may increase the total output of hemoglobin above the level due to the liver fraction alone. Whipple has also shown in his dogs, and we have observed in the clinic, that liver extract for pernicious anemia is essentially inert in anemia due to chronic blood loss, but upon supplementing it with a relative-

ly little whole liver, the effect in the dogs and in an occasional human case is greater than the influence of either alone. Clinical observations show that large amounts of liver can be effective in the regeneration of blood following chronic blood loss and in some other cases of "secondary" anemia, but that it is usually less potent and far less easy to take than iron salts. Sometimes liver will have little or no effect on anemias of ill-defined origin in which iron will produce rapid blood regeneration. The addition of liver, however, to the diet of a patient improving with iron can act sometimes to accelerate blood regeneration, especially as the hemoglobin approaches the normal level.

Iron apparently acts to produce blood regeneration by an effect additional to supplying the element for hemoglobin formation. It alone can not supply the loss from the body of material valuable for hemoglobin formation, but liver and kidney particularly, as well as other foods, contain material necessary for new hemoglobin fabrication. Although iron alone can often produce, with a satisfactory diet, excellent results, it is to be recognized that liver or potent substitutes with iron may cause maximal blood regeneration. If treatment with iron and liver, or a suitable substitute, is prescribed because the combination offers the greatest chance for the greatest improvement in anemic patients, some patients will take material that is unnecessary, and knowledge regarding the effectiveness and action of substances will not be obtained. Sometimes one can demonstrate clearly the influence of different materials by

feeding for periods of time first one and then another substance.

We have seen cases that were certainly not ones of pernicious anemia, with the red blood cells about 2,000,000 per cu.mm and the color index close to one, that responded to liver extract effective in pernicious anemia with rapid regeneration of the red blood cells to normal, but with only slight increase of the hemoglobin over a period of weeks. At that stage, however, iron caused rapid regeneration of hemoglobin. Cases also have been observed that were inert to alcohol precipitated liver extract, but in which whole liver slowly produced regeneration of the red cells to normal with some rise of hemoglobin. In these cases, upon the addition of iron, there followed a rapid rise of hemoglobin to normal. When iron alone is given the hemoglobin and the red blood cells often increase rapidly to normal. Sometimes the red blood cells rise quickly, for example from 3,000,000 to 4,500,000 per cu mm and the hemoglobin from 40 to 70 per cent. Without further treatment than iron and a satisfactory diet there may then be a very sluggish rise of the hemoglobin and red cells, but sometimes in such cases if whole liver is added, the hemoglobin rapidly rises to normal and the red blood cells promptly increase still further. It is thus desirable to learn the effect of different factors on blood regeneration in not only various sorts of anemias, but in anemias due to the same cause under varying conditions. Important conditions that may vary are the degree of anemia, the character of the red blood cells, the amount of reserve

supplies of blood-building materials in the body, the secretions of the stomach, and other states of the gastrointestinal tract

THE IMPORTANCE OF DIET

The diet of each patient with anemia must be carefully considered and individually prescribed, or adequate treatment will not be given. The relationship between diet and anemia was mentioned in the 17th century. Although the scientific foundations for the value of food for patients with anemia were laid by Menghini in 1746 and by Verdel in 1849 when they showed by feeding animals food rich in iron that this element could be increased in their blood, it is only within recent years that the importance of diet in causing or alleviating anemia has been broadly recognized. Even so, knowledge concerning the influence on blood formation of different sorts of food or substances they contain is in its infancy and there is need for a wider appreciation of the fact that anemia often can be wholly or partially related to the partaking of an unsuitable diet for a period of years.

A carefully obtained and detailed history concerning the patient's dietary habits throughout life often will suggest a reason for anemia and can lead to the selection of a desirable diet for a given case. The part played by chronic digestive disorders, such as colitis with diarrhea and achlorhydria with or without other altered physiological mechanisms in preventing the absorption or utilization of factors necessary for blood formation is always for evaluation. Temporary gross dietary deficiencies do not pro-

duce significant symptoms but departure from an optimal diet, even if slight, can produce ill health when operative over a long period of time and especially if combined with digestive disturbances. For example, it is common to observe women who eat little or no breakfast, a lunch composed chiefly of concentrated carbohydrate foods and a fairly satisfactory evening meal who have slight anemia and often constipation. In such cases, without other cause for the anemia than improper food, an ordinary well-balanced diet rich in fruits and green vegetables and containing ample animal protein not only can correct the anemia, but improve much more the patient's general sense of well being. Iron or liver or both may accelerate the improvement.

In known chronic vitamin deficiencies in man anemia is a symptom. The anemia may be dependent upon other factors than the lack of a given vitamin, but at times as in chronic scurvy in adults it can be related directly to the lack of vitamin C. In such instances iron and liver extract potent for pernicious anemia are not effective, but food rich in vitamin C can produce a reticulocyte response and rapidly lessen the anemia. Anemia can also arise from long-standing deficiency of protein and lessen when ample protein food is supplied.

These examples of ill-defined and distinct dietary defects simply hint at the many varieties of defective diets that can play a rôle in the production of anemia. In such conditions as well as in others, food alone, excluding liver or potent substitutes, can restore the blood to normal, although often in

such cases, iron with or without liver is necessary for effective or rapid results. In anemia, however, the body is probably often depleted in the products needed to build cells and hemoglobin; such occurs, for example, in chronic blood loss and in long-standing dysentery as well as when the food intake has been obviously chronically deficient in one or more respects. Iron and liver extracts indeed may produce great benefit, but in order to establish a completely normal state of affairs, other elements are required for the manufacture of blood which can be supplied by food for optimal nutrition. For example, we have demonstrated that patients with anemia from prolonged chronic blood loss treated with iron regenerate their blood more slowly when their diet is composed of crackers and milk than when it contains muscle meat, vegetables, and fruits.

It is only desired to indicate here that the greatest improvement in the anemic patient will be obtained when, in addition to distinctive therapy, attention is paid to the diet. The patient's weight, age, and state of his digestive system must be considered in prescribing the diet. Simply because diarrhea exists, the diet must not be abnormal in quality. In certain vitamin deficiencies, looseness of the bowels may be a result and the prolonged diarrhea may increase the cause. In such cases, the physical state of the food may need modification; but the diet should contain optimal quantities of food for the best possible nutrition. Certain foods may delay the digestion of other foods or upset the digestive functions; for ex-

ample, fat, except in small amounts in the diet of many pernicious anemia patients, often disturbs the digestive process as well as leads to an undesirable gain of body weight. One must not only consider for a given anemic individual the selection of food from the point of view of furnishing ample blood-building materials and supplying food for optimal nutrition, but also take into account the preparation of the food and the exact dishes to be served.

THE IMPORTANCE OF ATTENTION TO EVERY PHASE OF EACH CASE

Large amounts of whole liver, together with big doses of iron and an adequate well-balanced diet offer the greatest chance of improvement to the anemic individual. Such treatment, however, is of a "shot gun" nature and will not determine the exact importance and action of different factors. Treatment given routinely in this manner will tend to lead to neglect of all the aspects of the patient's case. Every phase of each case must be properly considered and treated and the patient, a human being himself, must never be neglected.

An example of where attention to the patient's conduct of life and his diet had a profound effect on his sense of well-being is as follows:

A man of 60 years of age with pernicious anemia in a state of remission for two years had taken regularly sufficient liver extract to maintain his red blood cells at about 47 million per cumm and hemoglobin at 80 per cent. He had suffered for the last eight months of this time from weakness, fatigue, various symptoms referable to an unstable vaso-motor system, considerable intestinal flatulence and

mental depression. Numbness in his hands developed, but varied greatly from hour to hour in its intensity. He had eaten an excess of sugar and concentrated starch food and it was believed that he had an intestinal carbohydrate indigestion. He, also, was confronted with anxiety regarding his children and had lost much sleep. Furthermore, he had discussed the symptoms of pernicious anemia with other individuals who suffered from this disease and believed he had a rapidly progressive disorder of his spinal cord. Prolonged optimistic talks with the patient, curtailment of the carbohydrate in his diet, regular moderate exercise and longer hours in bed at night, without change in the daily dose of liver extract caused within a few weeks pronounced improvement in his health. The numbness in his hands disappeared, the gastrointestinal tract functioned properly and his strength returned and co-

incidentally the hemoglobin increased over ten per cent and the red blood cells about 400,000 per cu mm.

In the future, more will be learned about the relation of the gastrointestinal tract to anemia and to other chronic disorders. Also knowledge will be broadened concerning the rôle that diet and substances contained in food play in the etiology and treatment of anemia. This will be accomplished from observations at the bedside expanded in the laboratory by not only trained clinical investigators, but by all practitioners of medicine. This is one of the most important ways that knowledge is obtained that leads to the alleviation of suffering and the prevention of disease.

Complement Fixation in the Diagnosis of Amebiasis*†

By CHARLES F. CRAIG, M A , M D., F A C P , Colonel, Medical Corps, U S. Army, *Washington, D.C*

BY the term "amebiasis" is meant the condition brought about in the human body by the invasion of the tissues of the intestines by *Endamoeba histolytica*, the ameba causing that type of dysentery called "amebic dysentery" Most unfortunately, from the standpoint of a clear understanding of the importance of this parasite as a cause of disease in man, the term "amebic dysentery" has, until quite recently, been synonymous with "amebiasis" in the minds of the vast majority of the medical profession In addition, the conception that infection with *Endamoeba histolytica* occurs only in the tropics and sub-tropics has led the profession far astray regarding the real importance of this parasite to human medicine throughout the world

As the result of many surveys by competent investigators, of all classes of people in many temperate regions, as well as in the tropics and sub-tropics, we know that *Endamoeba histolytica* is world wide in distribu-

tion and that, so far as the United States is concerned, from five to ten per cent of individuals harbor this parasite The percentage is far higher in some parts of our country, while it is somewhat lower in others, but a conservative estimate places the infection of the general population of the United States at about five to ten per cent. Fortunately, most of the individuals infected do not show marked symptoms of their infection, but clinical observations of infected individuals have shown that from 20 to 50 percent do have symptoms, and that in most such individuals proper treatment resulting in the elimination of the parasite, also results in the disappearance of the symptoms.

As long ago as 1891, Dock¹ demonstrated that amebiasis is not a tropical disease, and that amebic lesions of the intestine could be present in persons free from dysentery and with no history of the infection. The observations of Dock were confirmed in 1910 by Musgrave², who demonstrated at autopsy that marked ulceration of the intestine may occur even though no recognizable symptoms are noted, and it is well known that abscess of the liver may occur in individuals with no

*From the Department of Preventive Medicine and Clinical Pathology, Army Medical School, Washington, D C

†Read at the Baltimore Meeting of the American College of Physicians, March 25, 1931

history of diarrhea or dysentery. In 1921, I⁸ called attention to the atypical symptoms often present in individuals infected with *Endamoeba histolytica*, symptoms having little in common with the classical symptom-complex known as "amebic dysentery", and to the great importance of regarding the latter condition as the most severe result brought about by the invasion of the intestine by this parasite.

Within recent times, an immense amount of evidence has accumulated demonstrating that marked deviations from health may be produced by this parasite without dysentery ever occurring and it may be truly stated that for one case of amebic dysentery there are hundreds of cases of amebic diarrhea or other conditions due to the parasite. In those individuals showing no symptoms of the infection we must believe that an equilibrium has been established between the host and the parasite, and that the damage done by the parasite is repaired immediately. However, this resistance to the parasite may be broken down in various ways, so that the recognition of the infection and the elimination of the parasite is important, even in these more fortunate individuals.

Whether *Endamoeba histolytica* can live in the lumen of the human intestine without invading the tissues is a question now being carefully investigated, but personally, it is believed that in every individual harboring this parasite some injury to the tissues is produced, and that the amount of this injury directly influences the character of the symptoms present, or their absence. If comparatively few

amebae are invading the tissues of the intestine, symptoms may be entirely absent, the minute lesions produced by the amebae healing promptly, while, if larger numbers invade the intestinal walls, the symptoms may vary from those characteristic of mild invasion to those recognized as typical of the symptom-complex known as "amebic dysentery". The important fact to be borne in mind, from the recent studies of this infection, is that *Endamoeba histolytica* is world wide in distribution and is the cause of much invalidism hitherto unrecognized as being due to this parasite. As Lynch⁴ says "We have come, then, from knowing amebic dysentery as the disease produced by *Endamoeba histolytica*, to the point where this is recognized as the uncommon acute, or relatively acute, phase of the disease, while there exists in the population at large an incidence of latent infection conservatively estimated at from five to ten per cent, in many, if not all, of which it is the belief of careful and competent experienced men that there is a chronic low-grade disease of devitalizing quality but diagnosable only on finding the amebae."

The recognition of these latent infections with *Endamoeba histolytica* is most important and, at the present time, rests upon the demonstration of the parasite in the feces of the infected individual. When the services of a competent protozoologist, or of one trained in the study of the various species of amebae occurring in the intestine of man (of which there are no less than five species) is available,

NOTE. In two of the cases cited the Wassermann and Kahn tests gave four plus reactions and these remained so after the disappearance of the positive reaction for infection with *Endamoeba histolytica*

the diagnosis can be made, but there is great difficulty in differentiating the various amebae of the human intestine and such a differentiation can be made only by one with training and experience. *Endamoeba histolytica* is the only pathogenic ameba occurring in the intestine and hence has to be differentiated from the four other species of ameba that occur there, for a diagnosis of amebiasis based merely upon finding an ameba in the feces is absolutely worthless. The development of some method of diagnosis which would eliminate, if possible, the necessity of differentiating the amebae, would obviously simplify the problem, and it has been with the hope of doing this that I have endeavored to apply the principle of complement fixation to the diagnosis of amebiasis. It has been found possible to do this and in previous publications^{5,6,7} I have described such a test and the results obtained with it.

As regards the technique it may be stated briefly that it follows the standard method for the complement fixation test for syphilis used in the U S Army laboratories. The human hemolytic system is used and the blood sera are inactivated by heating at 56°C for one-half hour. The antigen used is an alcoholic extract of cultures of *Endamoeba histolytica* grown upon the Boeck-Drbohlav medium.

MATERIAL

The greater number of the individuals tested have been patients in Walter Reed U S Army General Hospital where the test is now used as a routine procedure in suspicious cases. The material has included pa-

tients suffering from a great variety of disease conditions and in addition numerous normal persons have been used as controls. The result of each test is checked by microscopic and cultural examinations of the feces of the individuals tested for the presence or absence of *Endamoeba histolytica*, and the results reported in this communication have all been checked by such examinations.

RESULTS OF THE TEST

Considerably more than 1000 individuals have been tested to date, but this report will concern only those tests in which the feces have been checked for the parasite, numbering 786, of which 110, or 13.9 per cent, gave a positive reaction, while 676, or 86 per cent, gave a negative reaction.

In the vast majority of cases the reaction with this test is very clear cut, being either three plus or four plus when read on a four plus scale. Of the 110 positive cases, no less than 91 gave a four plus reaction and 17 a three plus reaction. It should be remembered in considering the number of positive cases that many of the patients at the Walter Reed General Hospital are soldiers or officers who have served in tropical regions, and that in the vast majority of cases tested there were symptoms indicating some disease condition located in the gastro-intestinal tract.

In the 110 positive cases, a check of the feces for *Endamoeba histolytica* resulted in the demonstration of this parasite in 94 cases, or 85.4 per cent. In 16, or a little over 14 per cent, we were unable to find the parasite, although this negative finding cannot

be considered as conclusive owing to the fact that in most of these cases it was not possible to make more than one or two examinations of the feces. It has been definitely shown that a single examination of the feces is often negative in positive cases and that a single examination demonstrates only about one-third of the total infections with this parasite.

Of the 94 positive cases showing the presence of *Endamoeba histolytica* in the feces, 66 showed infection with *Endamoeba histolytica* alone; 12 were mixed infections with *Endamoeba histolytica* and *Endamoeba coli*; 6 with *Endamoeba histolytica* and *Endamoeba nana*; 2 with *Endamoeba histolytica*, *Endamoeba nana* and *Endamoeba coli*, 2 with *Endamoeba histolytica* and *Chilomastix mesnili*; 4 with *Endamoeba histolytica* and *Giardia intestinalis* and 2 with *Endamoeba histolytica* and *Trichomonas hominis*.

There were 676 individuals tested giving a negative result, and of these, *Endamoeba histolytica* was found in 8 cases or 1.1 per cent. Three of these were acute cases of amebic dysentery; one was a case of abscess of the liver; three showed indefinite gastro-intestinal symptoms, while one was symptomless. From these findings it is evident that all persons infected with this parasite do not give a positive reaction but that the percentage of such individuals is apparently very small.

Of the 676 patients giving a negative reaction no less than 220, or 32.5 per cent, were infested with other species of protozoa. There were 100, or 14.7 per cent infested with *Endamoeba coli*; 64, or 9.9 per cent,

infested with *Endamoeba nana*; 3, or 0.4 per cent, infested with *Iodamoeba williamsi*; 26, or 3.8 per cent, with *Chilomastix mesnili*; 16, or 2.3 per cent, with *Trichomonas hominis*, and 11, or 1.6 per cent, with *Giardia intestinalis*. There were 14 mixed infestations with *Endamoeba coli* and *Endamoeba nana*; 6 with *Endamoeba coli* and *Chilomastix mesnili*; 4 with *Endamoeba coli* and *Giardia intestinalis*, and 3 with *Endamoeba coli* and *Trichomonas hominis*.

The infestation of the intestine of man by species of amebae other than *Endamoeba histolytica* does not result in a positive complement fixation reaction. Thus, of the 676 patients giving a negative reaction no less than 164, or 23.5 per cent, were infested with some other species of ameba, but none of these cases gave even a partial reaction with the test.

As practically all of the 676 individuals giving the negative reaction were patients in a large general hospital and were suffering from a wide range of acute and chronic disease conditions, it is justifiable to conclude that this test is not positive in other diseases with the exception, as noted later, of certain rare cases of syphilitic infection.

DISAPPEARANCE OF THE COMPLEMENT FIXATION REACTION AFTER TREATMENT

It has been our invariable experience that after treatment resulting in the disappearance of *Endamoeba histolytica*, the positive complement fixation reaction becomes negative. The rapidity with which the reaction becomes negative depends on the

efficiency of the treatment. The earliest disappearance of the reaction after cessation of treatment resulting in the disappearance of *Endamoeba histolytica* from the stools has been five days and the longest period 60 days. In the longer periods it is probable that the reaction disappeared much more rapidly than indicated, as in some of these cases tests were not made until a long period had elapsed. In most of the cases the reaction disappears within three weeks after the disappearance of the organism from the feces following treatment. In several cases relapses have occurred and the reaction has again become positive, becoming negative again after proper treatment. The disappearance of the positive reaction after treatment demonstrates the specificity of the reaction. It has been noted that in cases giving a positive Wassermann and Kahn reaction that the complement fixation reaction for *Endamoeba histolytica* has become negative while the Wassermann and Kahn reactions remain positive. Table I illustrates the results obtained with the complement fixation test before and after treatment, the cases selected being those most typical of the varying results as regards time of disappearance of the reaction.

RELATION OF THE WASSERMANN AND KAHN REACTIONS

The antigen used in the complement fixation test for infection with *Endamoeba histolytica* is an alcoholic extract of cultures of the organism mixed with the bacteria which may be growing with it in the cultures and it also contains some material derived

from the culture medium itself. Early in our work it was believed that the results obtained with the test might be due to a non-specific substance present in the extract, similar to those in extracts used as antigens for the Wassermann and Kahn tests. In order to obviate such a source of error, and ascertain whether the positive results were due to syphilis, all of the sera tested have been subjected to both the Wassermann and Kahn tests in addition to the complement fixation test for *Endamoeba histolytica*. This check has shown that 15, or 13.6 per cent, of the 110 individuals giving a positive reaction with the complement fixation test for *Endamoeba histolytica* also gave a positive Wassermann and Kahn reaction, while 95, or 86.3 per cent, gave a negative Wassermann and Kahn reaction. On the other hand, of the 676 individuals giving a negative reaction with the complement fixation test for *Endamoeba histolytica*, 56, or 8.2 per cent, gave a positive Wassermann and Kahn reaction, while 620, or 91.7 per cent, gave a negative Wassermann reaction and 618, or 91.4 per cent, gave a negative Kahn reaction. It will thus be seen that about five per cent more individuals gave a positive Wassermann and Kahn reaction in those giving a positive result with the complement fixation test for *Endamoeba histolytica* than in those giving a negative result. It was also significant that of the 15 individuals giving a positive reaction with all three tests, no less than nine failed to show *Endamoeba histolytica* in the feces, although it must be stated that in these cases not more than two

examinations were made of the feces. If we admit that all found negative were free from infection with *Endamoeba histolytica*, it would follow that the positive reactions were due to infection with syphilis, but in interpreting these figures it should be remembered that a considerable number of the sera tested were selected at random from specimens submitted to the Serological Laboratory of the Army Medical School, for the Wassermann and Kahn tests. However, the fact that a considerably larger percentage of cases giving a positive reaction with this test also gave positive Wassermann and Kahn reactions, taken with the failure to find *Endamoeba histolytica* in the feces in more than half of these cases, leads us to conclude that, in rare instances, patients suffering from syphilis may give a positive result with this test and that this disease should be eliminated, if possible, in patients giving a positive reaction, unless the result is supported by finding the parasite in the feces.

PRACTICAL VALUE OF THE COMPLEMENT FIXATION TEST FOR AMEBIASIS

At the present time the practical value of the test we have been discussing is limited by the difficulty of preparing the antigenic extract, which has to be prepared from a large number of cultures of *Endamoeba histolytica*, and the difficulty of maintaining these cultures is not inconsiderable even to one accustomed to cultivating this organism. However, this difficulty is not insuperable, but the technique of the test is such as to

render it impossible of application except in laboratories where the services of a protozoologist and a serologist are available. As shown by the results which have been obtained with the test, it is of considerable value in the diagnosis of cases of amebiasis, and the physicians at Walter Reed General Hospital, for whom the tests have been made, are unanimous in the statement that it has been of practical value to them in diagnosis. Efforts have been made to simplify the method of preparing the antigenic extract, or to render it more powerful, but to date these efforts have been in vain, so that it cannot be said that at the present time the test is on the practical basis that a complement fixation test should be, before it is relied upon *alone* in the diagnosis of a specific infection. However, it is felt that the technique will be simplified and that eventually the test will be of greater practical value.

CONCLUSIONS

The following conclusions have been justified by the results of the complement fixation test for amebiasis obtained to date

- 1 There occur in the blood serum of individuals infected with *Endamoeba histolytica*, specific substances which can be demonstrated by complement fixation when alcoholic extracts of cultures of this parasite are employed as antigens

- 2 These complement fixing bodies disappear from the blood serum after treatment resulting in the disappearance of *Endamoeba histolytica* from the feces of the infected individuals

3 Individuals free from infection with *Endamoeba histolytica* very rarely give a positive reaction, and in the very small percentage of cases in which infection with this parasite could not be demonstrated it is probable that the failure to demonstrate it was due to an insufficient number of examinations of the feces

4 Individuals infested with *Endamoeba coli*, *Endamoeba nana*, *Iodamoeba wilhamsi*, *Chilomastix mesnili*, *Trichomonas hominis* or *Giardia intestinalis* do not give a positive reaction with the complement fixation test

5 With the exception of rare cases of syphilis, the complement fixation test for amebiasis does not occur in individuals suffering from other infestations or diseases

6 Positive complement fixation reactions occur in individuals suffering from symptoms of infection with *Endamoeba histolytica*, and also in those in whom symptoms are absent, i e, the so-called "healthy carrier" of the parasite. It has been noted that when symptoms are very acute the complement fixation reaction is sometimes absent or weak

Pathological Classification of Goiter and Its Clinical Significance*†

By WM CARPENTER MACCARTY, M D , F A.C P., *Rochester, Minnesota*

IN 1912,² a report of more than two thousand goiters revealed that they divided themselves into two great groups· those which were thyroid shaped and those which were nodular. Both groups were then studied from the standpoint of their structural and functional units and these were correlated with the clinical pictures. Since then, 32,479 goiters have been examined grossly and microscopically. In this large amount of material universal facts and principles have been sought in the hope of giving to practicing physicians and surgeons some simple clinical classification based on gross and microscopic characteristics which have become known to be associated with definite symptoms

It is interesting to note what Boothby,¹ a clinical physiologist, has said about the classification of goiter " . . the anatomic changes (except infection and malignancy) are not primary and, therefore, are not the fundamental cause of the various diseases of the thyroid gland. In consequence it seems advisable to attempt the interpretation of thyroid disease and the ac-

companying pathologic changes in the light of the changes in physiologic activity rather than in the terms of pathologic anatomy. . . To meet the needs of the clinician, however, a classification of thyroid disease cannot with the knowledge at present available, be expressed entirely in terms of physiologic activity any better than in terms of gross or microscopic pathology; nor can it be based entirely on etiology."

It is a recognition of this fact over many years that has led to the continued and constant study of gross anatomy, histology and cytology in the series reported. Clinical classifications always become more intelligible when the finer structures, structural relationships, functions, and functional relationships are clearly understood. In this study an attempt has been made to present the fundamentals of structure, and to correlate them with the well-known clinical manifestations of disease of the thyroid gland.

The structural units of the thyroid gland, under all conditions, are very definite and constant. These may be seen in the accompanying diagrammatic drawing (figure 1). Thus in the early stages of fetal development one finds in the neck a mass of cells without acinic or follicular arrangement

*Read before the American College of Physicians, Baltimore, Maryland, March 26, 1931

†From the Section on Surgical Pathology, The Mayo Clinic, Rochester, Minnesota

(figure 1, *a*). These cells are the undifferentiated fetal thyroid gland. Later they assume acinic form (figure 1, *b*). During this change the whole mass of fetal cells assumes the gross form of the adult thyroid gland. During postnatal life this form is maintained unless altered by pathologic conditions. The normal adult thyroid gland is composed of acini which are approximately spheroidal in shape, lined by low cuboidal or spheroidal cells (figure 1, *c*). The lumen of the normal acinus is filled with a "colloid" material. There is fairly constant uniformity of size

of the acini, although one occasionally finds acini which are fetal in size.

In my experience there are only four types or conditions of acini which are sometimes associated with abnormal or pathologic signs and symptoms. These are the fetal acinus (figure 1, *b*) one finds in adenomas, the dilated acinus (figure 1, *d*) found in the simple colloid goiter, the acinus lined by hypertrophic columnar cells (figure 1, *e*) seen in association with hyperthyroidism which occurs in both thyroid shaped goiters and nodular goiters, and the acinus lined by atrophic cells seen in myxedema and cretinism.

FIG 1 Diagrammatic representation of all types of hypertrophic goiters (with the exception of pure inflammations and malignancies), *A*, hypertrophic symmetric goiters, *B*, hypertrophic nodular goiters, *a*, undifferentiated fetal thyroid cells, *b*, typical fetal acinus, *c*, normal adult acinus, *d*, distended acinus filled with colloid and lined by spheroidal or "cuboidal" epithelium, *e*, acinus lined by hypertrophic or "columnar" epithelium. In the lower portion of the diagram is the relative size of the normal thyroid gland.

ANATOMIC DESCRIPTION

In figure 1, *A* represents thyroid shaped goiter. 1. Hypertrophic* simple or colloid goiter (*Ad*) is one in which there is a symmetric hypertrophy of the whole gland. The acini are dilated or enlarged, lined by low cuboidal cells, and contain colloid. In some of such goiters one also finds fetal and normal acini (*a, b, c*). 2. Hypertrophic parenchymatous goiter (*Ae*) is one in which there is symmetric hypertrophy of the whole gland. The acini are lined by columnar cells and may or may not contain colloid. They may vary greatly in size. All or some of the acini give evidence of parenchymatous hypertrophy. There may be some acini of the fetal (*a, b*), normal (*c*) and dilated type (*d*).

In figure 1, *B* represents nodular goiter. Hypertrophic nodular goiters are due to the presence of spheroidal circumscribed masses which usually can be shelled out. They vary in size; they may be microscopic or many centimeters in diameter. The spheroidal masses (adenomas**) are primarily

*Much confusion arises even in the purest science from lack of definition of terminology. In this paper the term "hypertrophy" whenever used means increase of size, that is, a hypertrophic thyroid gland signifies only that the thyroid gland is enlarged above the normal size. The term applied to cells means the cells are enlarged.

**The term adenoma is usually applied to masses because they are circumscribed and composed of newly formed glandular tissues. Some confusion in the literature has occurred because of disputes over whether this newly formed tissue is circumscribed or not. As a matter of fact it usually is but

composed of fetal acini (*b*) usually separated by loose connective tissue. There may be present others of the different types of acini (*a, c, d*) and in very rare instances acini with hypertrophic cells (*e*). Usually these spheroidal masses show signs of degeneration, which is the result of hemorrhage which destroys the tissues. Such hemorrhagic portions vary in size from petechial points to that in which the whole mass is involved. Such a mass may, therefore, be a cyst containing a hemorrhagic fluid and, in some instances, a brownish clear fluid containing crystals of cholesterol, depending on the length of time since the initial hemorrhage and destruction. In some instances, when the hemorrhage has been small, the region of destruction undergoes repair, and is filled in with scar tissue which sometimes becomes calcified. Small hemorrhagic portions often appear as yellowish spots, this being due to the presence of fatty degeneration of the cells to which the circulation has been impaired. Sometimes the spots are dark blue or purplish-blue, due to an early stage of disintegration of extravasated hemoglobin.

The glandular tissue surrounding the spheroidal masses may present any of the acini seen in the hypertrophic thyroid shaped goiters (figure 1, *A*). An anatomic classification follows

one does find areas in some thyroid glands (particularly pathologic) which are not circumscribed. This is particularly true of the rare thyroiditis. It seems that the discussion is without practical importance and serves merely to confuse working knowledge.

- A (Thyroid shaped) { Hypertrophic colloid goiters
Hypertrophic parenchymatous goiters
Atrophic parenchymatous goiters
- B (Nodular) { Adenomatous goiters without parenchymatous hypertrophy
Adenomatous goiters with parenchymatous hypertrophy { intra-adenomatous
extra-adenomatous
Adenomatous goiters with parenchymatous atrophy { intra-adenomatous
extra-adenomatous
- C Thyroiditis { acute { nontuberculous
chronic { tuberculous
- D Malignancy { carcinoma
sarcoma } usually in degenerating adenomas
epithelioma }
- E Accessory thyroid tissue

The relative frequency of pathologic conditions of the thyroid gland is as follows

ministration of iodine, the parenchymatous hypertrophy usually disappears, although some or all of the symptoms

	Specimens
Hypertrophic colloid goiter (figure 1, <i>Ad</i>)	800 (24 per cent)
Hypertrophic parenchymatous goiter (figure 1, <i>Ae</i>)	9,520 (293 per cent)
Hypertrophic nodular goiters (figure 1, <i>B</i>)	21,787 (67 per cent)
Without parenchymatous hypertrophy (figure 1, <i>Be</i>)	18,444 (846 per cent)
With parenchymatous hypertrophy (figure 1, <i>Bc</i>)	3,343 (154 per cent)
Carcinoma	267 (08 per cent)
Sarcoma	7
Epithelioma	7
Tuberculosis	22
Undifferentiated thyroid gland (figure 1, <i>a</i>)	58
Hypertrophic fetal thyroid gland	1
Total number resected thyroid glands (1911-1930 inclusive)	32,479

CLINICAL CORRELATION

Enlargement of the thyroid gland of any type, especially when part of it is substernal, is frequently associated with symptoms and signs of pressure on the respiratory and circulatory apparatus

The clinical syndrome known as hyperthyroidism, and frequently spoken of as a toxic condition, is associated with parenchymatous hypertrophy regardless of whether the goiter is thyroid shaped or nodular. After the ad-

ministration of iodine, the parenchymatous hypertrophy usually disappears, although some or all of the symptoms and signs may remain. Thus, a goiter which previous to the administration of iodine may give evidence of typical parenchymatous hypertrophy presents itself as a hypertrophic colloid goiter after the administration of iodine.

Parenchymatous atrophy is associated with hypothyroidism, which manifests itself in two forms, cretinism and myxedema, and these conditions may occur in thyroid shaped thyroid glands or goiters, or in nodular goiters. In fact, a clinical condition of hypothy-

roidism is sometimes found even in the presence of parenchymatous hypertrophy. Thus, a cretin's thyroid gland may present the histologic picture of typical exophthalmic goiter. There is apparently a quantitative as well as qualitative relationship between parenchymatous hypertrophy and the clinical syndromes of hyperthyroidism and hypothyroidism.

As a result of these generalizations, the clinician may visualize and palpate the neck, determine if possible the

form of the enlarged thyroid gland, decide whether it is thyroid shaped or nodular, and then determine whether the patient has or has not signs and symptoms of hyperthyroidism, hypothyroidism or pressure, and correlate their presence or absence with the diagrams (figure 1). Thus, in a very high percentage of instances, he should be able to forecast the gross and histologic pathologic characteristics. There will be a small error because even a thyroid shaped gland may con-

FIG. 2 Relative frequency of parenchymatous hypertrophy in goiters from 1911 to 1930 inclusive, aa, number of resected goiters; bb, percentage of simple nodular goiters without parenchymatous hypertrophy, cc, percentage of simple hypertrophic goiters with parenchymatous hypertrophy; dd, percentage of nodular goiters with parenchymatous hypertrophy; ee, percentage of simple hypertrophic colloid goiters

tain a small impalpable adenoma. There is also the possibility that hyperthyroidism or hypothyroidism may not be sufficiently marked to be recognized clinically. Again, it is possible occasionally to mistake other obscure toxic conditions for hyperthyroidism.

It is of interest, and may be of future importance to note, that during this study over a period of twenty years (1911 to 1930 inclusive), there have been some variations in the relative frequency of the presence of parenchymatous hypertrophy, both in the thyroid shaped goiters and the nodular goiters. Figure 2 shows the percentage of hypertrophic colloid goiters, hypertrophic parenchymatous goiters, and parenchymatous hypertrophy in nodular goiters. Thus, there is an apparent increase in the presence of parenchymatous hypertrophy in both groups of goiters, beginning about 1921. The studies during the whole period of twenty years were made under the guidance of the same staff, and al-

though acuity of vision might have increased with experience it does not seem that the variation should be quite so pronounced. This increase suggests, as H. S. Plummer³ has frequently pointed out, that there might be epidemics of hyperthyroidism. Further regional studies are being made to substantiate or refute this possibility.

It is the object of this short review of a very large amount of material to give the active practicing clinician the fundamental universal facts which have so frequently been confused by elaborate discussions, dissertations, articles, and monographs on the subject of goiter.

The Heart in Hyperthyroidism*†

By HENRY M. THOMAS, Jr., *Baltimore, Md*

IN discussing the heart in hyperthyroidism I shall try to take up clinical points about which there has been much controversy in the past. In order to establish a proper background I shall briefly summarize the history of this subject

In the first allusion to hyperthyroidism made by Parry¹ in 1786 (and published posthumously in 1825) eight cases of a peculiar heart disease, attended by exophthalmos and thyroid enlargement were described. He evidently considered the disease primarily a cardiac affection with secondary exophthalmos and enlargement of the thyroid gland. Although Adleman² in 1829 spoke of "Kropfherz," the Englishmen, Graves,³ Stokes,⁴ Marsh⁵ and McDonnell,⁶ who seem to have written separately between 1840 and 1855 about the same group of cases, still thought the enlargement of the thyroid gland and the exophthalmos came after the heart trouble. In this country Markham,⁷ in 1858, reported "affection of the heart with enlarged thyroid and thymus glands and prominence of the eyes." Moebius⁸ and later Horsley⁹ and Kocher¹⁰ and Müller¹¹ recognized

the part played in the syndrome by the thyroid, but an accurate conception of the heart changes was far from being elaborated at that time. The surgeon, Rose,¹² working at Zurich, wrote a long paper in 1877 pointing out the importance of considering the heart in operations on the thyroid gland. He thought that the goiter compressed the trachea and thus, by interfering with the breathing, placed the right heart under strain. His method of treatment was to perform a preliminary tracheotomy to relieve the heart of this particular form of strain. Thus the so-called goiter heart of Rose was a heart enlarged and weakened purely by a mechanical obstruction. Many other writers noticed decompensation of the heart in patients with large goiters. These observations were practically all made in the goiter regions in Switzerland, the Tyrol, Bavaria, etc., by Wolfier,¹³ Wette,¹⁴ Thomas, Schranz¹⁵ and others. Finally Kraus,¹⁶ in 1899, brought forth his conception of the so-called neurotic or thyrotoxic heart. His view has been generally accepted although there is still some confusion about those cardiac conditions which occur in patients with goiters which are obviously not toxic. I allude to such frank cases as the heart in cretins with goiters, etc. It is likely that the authors from goiter districts

*Read before the Committee on Cardiac Clinics, New York Tuberculosis and Health Association, January 27, 1931.

†From the Thyroid Clinic, Johns Hopkins Hospital.

are describing cases of myxedema heart without clearly differentiating them from hyperthyroid heart. Even as late as 1926, European writers (Meyer and Sulger,¹⁷ and Andrassy) have considered the cardiac disturbances in goiter due to pressure on the trachea, the great vessels, or the vagus and sympathetic nerves of the neck.

In America we have come to a fairly clear differentiation between hyperthyroid heart and myxedema heart and most of us still maintain open minds as to the occasional occurrence of a purely mechanical thyroid heart. Of these three forms of thyroid heart disease, by far the most common is the one associated with hyperthyroidism, and, therefore, I shall limit my discussion to this variety. We do not believe that there is any essential difference between hyperthyroidism from a nodular goiter and that from the diffuse goiter of Graves' disease. The fact that a nodular goiter may exist for a long time before cardiac symptoms develop has led some people to believe that nodular goiter may damage the heart. We have seen no proof of this and are inclined rather to believe that a mild degree of hyperthyroidism which has existed for some years finally becomes evident when the cardiac reserve has been diminished.

If I may state the conclusion at the outset of my discussion, I can then build up the full clinical picture in what I think is its logical sequence. This conclusion is

The primary effect of hyperthyroidism on the circulatory system is tachycardia. This tachycardia is effected in several ways

(a) By additional work associated

with an increase in blood flow caused by the elevated body metabolism;

(b) By stimulation of the accelerator fibers of the sympathetic nervous system;

(c) By direct action of an excess of thyroxin on the heart muscle cells.

I can not substantiate with experimental data the statement that the heart rate goes up in response to an elevated metabolic rate. Some years ago Sturgis¹⁸ pointed out that the increase in heart rate paralleled the elevation in the metabolic rate. But it is perfectly obvious that the same factor which had an effect on the metabolism might quite independently have an effect on the heart rate. In this connection it is interesting to consider the effect of thyroid medication on cases of heart block. Willius,¹⁹ and Aub and Stern²⁰ have reported the results of such treatment and we have had one case in our clinic. Briefly, the ventricular rate is unaffected by large doses of thyroxin although the metabolism goes up and the blood flow increases, the auricular rate, on the other hand, which is still under the control of the vagus and accelerator nerves, increases from 70 to 120. I do not believe that any final conclusions can be drawn from these facts, and I am under the impression that most observers believe that the usual response to the increased blood flow is an increased heart rate. There are various indications of the effect of the accelerator fibers on the tachycardia of hyperthyroidism. Ergotamine has been used to block the accelerator impulses and in some cases a slowing of the heart rate has been accomplished. The over-activity of the sympathetic sys-

tem in other ways has been given as circumstantial evidence of over-activity of the accelerator fibers. But the effect of thyroxin on the heart muscle itself has been clearly demonstrated by Lewis and McEachern²¹ Experiments with isolated hearts from animals which have been rendered hyperthyroid by feeding with thyroid extract show that these heart muscle preparations maintain a rapid rate of contraction (26 to 144 beats per minute faster than normal preparations under the same conditions) for as long as ten hours, the longest period over which they have been observed as yet. This suggests an increase in the heart muscle cell metabolism

Now, as the hyperthyroid tachycardia persists, however it may have been produced, the rest of the signs and symptoms of thyroid heart gradually come into the picture. If the patient is a young, healthy individual, his heart will be able to stand even an excessive degree of hyperthyroidism without evidence of congestive heart failure. If he is past middle age and his heart therefore is out of training and unused to the excessive strain which the constant running around of young individuals produces; or, on the other hand, his heart is the site of valvular or arteriosclerotic heart disease with diminished cardiac reserve, then, sooner or later, congestive heart failure will occur. In practically every instance this is associated with, or preceded by, auricular fibrillation. It is not clearly known whether auricular fibrillation is purely a failure of the auricles to respond to too much work or whether thyroxin adds a degree of irritability to the muscle fibers which

causes them to fibrillate sooner than otherwise. The fact that young, healthy hearts rarely fibrillate even under the most severe degree of hyperthyroidism lends weight to the idea that it is purely an over-work phenomenon which occurs only when the cardiac reserve has been overdrawn. Seven and a half percent of the cases of auricular fibrillation recorded in the Heart Station of the Johns Hopkins Hospital were patients suffering from hyperthyroidism (McEachern).

Among the cases which develop auricular fibrillation some do not show signs of congestive heart failure. Hamilton²² has stressed this point and carefully described the clinical picture of those with congestive failure. He points out that in his series of 50 such cases, exophthalmos was usually absent, the thyroid gland was often normal in size, the tremor and nervousness almost never occurred. In recognizing this condition from the other causes of congestive heart failure, he stresses (a) tachycardia which does not respond as well as would be expected to complete rest and digitalization, (b) history of unexplained loss of about 30 pounds, (c) history of a surprisingly long duration of complete disability associated with gross signs of heart failure, (d) elevated BMR (he states that non-thyrotoxic congestive heart failure cases may have a BMR of +64 which will return to normal when the heart failure is relieved). The average age of this series of Hamilton's cases was 50 years. One might suppose that this group (like many cases of so-called toxic adenoma) is comprised of patients whose cardiovascular systems were damaged to a

degree whereby slight hyperthyroidism (so slight that the characteristic clinical signs of exophthalmos, goiter, tremor and restlessness are hardly noticeable) could cause myocardial insufficiency. This series of Hamilton's brings out the fact more clearly that when congestive heart failure occurs in hyperthyroidism, the failure is brought about, not by excessive hyperthyroidism, but by moderate or slight hyperthyroidism superimposed on an inferior cardiovascular system

Whether or not dilatation and hypertrophy occur in uncomplicated thyroid heart is still an unsettled question. Those who think that hypertrophy of the ventricles occurs can find confirmation in the experiments on laboratory animals. Cameron and Carmicheal²³ in 1921 produced hypertrophy of the heart in rats by feeding thyroid extract. Last year Simonds and Brandes²⁴ reported their work on dogs. They found that the hypertrophy involved all the chambers of the heart with a slightly greater proportional increase in the left ventricle. Also most accounts of the postmortem findings of the thyroid heart describe hypertrophy in a large number of the cases and of 27 thyroid hearts studied in the Pathological Department of the Johns Hopkins Hospital by McEachern and Rake,²⁵ 16 had definite hypertrophy. Lewis²⁶ reported 12 cases, in all but three of which the heart weighed over 300 grams. Means and Richardson²⁷ also have reported the necropsy findings in 12 cases. Their series showed but little hypertrophy. The clinical evidence is not clear cut. Hurxthal²⁸ made careful cardiac measurements on thyroid patients before

and three months after operation. He found no contraction in the size of the heart, from which he inferred that there had been no previous enlargement. He further compared 100 cases of toxic goiter with 100 cases of non-toxic goiter and, after making correction for the transverse diameter of the chest and body weight, he concluded that the average transverse diameter of the heart in the toxic group exceeded that of the non-toxic group by only 0.49 cm. It seems likely to us that the hypertrophy has occurred only as a result of a well marked and fairly profound hyperthyroidism. We can say definitely that when congestive heart failure occurs dilatation of the ventricles is very likely to be found and this dilatation disappears entirely when the hyperthyroidism has been removed.

The blood pressure shows a slight elevation in the systolic pressure and diminution in the diastolic pressure. If a pronounced degree of hypertension is encountered it is likely that this condition will persist or become worse after operation. The electrocardiogram shows an unusually prominent T wave and Hamberger²⁹ has noted a parallel in the degrees in basal metabolic rate and the height of the T wave following iodine medication and thyroidectomy.

If the hyperthyroidism is successfully terminated by subtotal thyroidectomy and adequate post-operative treatment is observed, the heart will, sooner or later, return to the state in which it was found at the beginning of the hyperthyroidism, allowing only for changes which would have occurred in a similar length of time under other

conditions This statement is a brave one. Let me show a condensed chart of such a patient.³⁰ (See chart 1).

Careful search for pathological changes in the hearts of patients dying from hyperthyroidism has yielded very inadequate findings. Various reports have been made noting changes in the heart muscle and these reach their high point with Goodpasture's³¹ account of two cases which showed degeneration and necrosis of the heart muscle fibers. Current opinion is that patients dying from thyrotoxic heart failure show a variety of inconstant minor lesions, none of which can sure-

ly be ascribed to hyperthyroidism. Some of the changes described are cardiac dilatation and hypertrophy, slight round cell infiltration and hyaline and fatty degeneration of the muscle fibers. An exhaustive examination of all the hearts of patients dying with hyperthyroidism at the Johns Hopkins Hospital has recently been made by McEachern and Rake²⁵. This work is soon to be published in a monograph form. Stated briefly their conclusions are that no pronounced pathological change is produced in the heart by hyperthyroidism.

If you will accept the foregoing

--- Pulse Rate, --- Body Temperature, --- Weight, [diagonal lines] Digitalis, [white] Te. Digitalis, [cross-hatched] Quinidine Sulfate

CHART I

Following the partial lobectomy the patient insisted on returning home before the auricular fibrillation had been interrupted. During the 13 months at home on digitalis, under the direction of his local physician, he continued to fibrillate and gradually went down hill. During his second stay at the hospital on rest, digitalis and quinidine, he excreted 33 pounds of fluid in 8 days and reverted to normal rhythm on the 8th day. Since September 12, 1928, he has done full manual labor as a track man on the railroad without the loss of a single day from sickness and without taking either digitalis or quinidine. (This chart was drawn by Mr. Charles McCurdy Gray, a member of the post-graduate class of the Johns Hopkins Medical School. Reprint from Bulletin of the Johns Hopkins Hospital, 1929, xlviii, 1-16)

hypothesis of the heart in hyperthyroidism the road to proper treatment will be quite clear. The first principle is that until congestive failure occurs no specific treatment for the heart is indicated; the second principle is that when once congestive heart failure has occurred it should be treated like any other form of congestive heart failure. I should like to make one exception to this statement and warn against the pre-operative use of quinidine for auricular fibrillation. The reason for this is that in the face of hyperthyroidism a fibrillating heart can be better controlled by digitalis than a heart with a regular mechanism. For example the ventricular rate of a case of auricular fibrillation in hyperthyroidism can be slowed under digitalis to 70 or 80 or 90 beats to the minute and the circulation greatly improved in this way. If, then, this digitalized heart is made to revert to normal mechanism by quinidine the slowing effect of digitalis may be lost and the rate suddenly jump up to 160 or 180. I have seen one such case in which just such a change took place, followed in the course of a few hours by exitus. When suitable therapeutic measures have been applied for relief of the heart failure the more important treatment of the hyperthyroidism can be undertaken. One must not be too cautious as to surgical procedures in cases of this kind as they are surprisingly well borne by these patients and they alone offer permanent relief.

Friedrich Muller and others have made the statement that iodine occasionally has a deleterious effect on the heart muscle. Laboratory animals have

been given relatively enormous doses of iodine with the production of slight pathological changes in the heart muscle, noticeable by microscopic examination. In the Johns Hopkins Cardiographic Laboratory a number of observations have been made on normal individuals before and after taking large doses of Lugol's solution^{32,33}. No changes were found in the electrocardiographic tracings or in other heart examinations in this series despite the fact that several of the individuals proved to be hypersensitive to iodine and suffered from varying degrees of skin eruptions and gastro-intestinal upsets. Dr John T. King, Jr.,³⁴ observed a case of an elderly woman suffering from nodular goiter with hyperthyroidism. After four days of rest in bed and Lugol's solution, ten minims three times a day, her heart rate became absolutely irregular. The Lugol's solution was discontinued and, in three days, the heart returned to normal rhythm. Of course this one case is not conclusive, but it illustrates very well my feeling in this matter. I believe that to a thyrotoxic heart iodine may be the additional factor which causes the final break. It seems quite likely to me that most of the cases of so-called iodine hyperthyroidism (Jod-Basedow) are in reality iodinism superimposed on hyperthyroidism.

We finally may conclude that the heart, like the rest of the body, responds to hyperthyroidism by being speeded up. Given a normal young cardiovascular system, this speeding up is a matter of little or no consequence. On the other hand, given a heart which is weakened by advancing age or heart disease and then the constant accelera-

tion from hyperthyroidism frequently leads to congestive heart failure. In either instance removal of the hyperthyroidism allows the heart to regain, both functionally and structurally, its pre-hyperthyroid condition.

I wish to express my indebtedness for criticism and suggestions during the preparation of this paper, to Dr Donald McEachern of the Johns Hopkins Hospital Medical House Staff, whose original work and whose familiarity with the literature on this subject made his help of great value

Medical Aspects of Peptic Ulcer*

By ALBERT F. R. ANDRESEN, M.D., F.A.C.P., *Brooklyn, New York*

IT is almost necessary to make an excuse for writing about peptic ulcer. Medical literature of the past twenty years has been filled with articles on this subject, volumes have been written about it and a verbal war between the advocates of medical and surgical treatment is still being waged with great intensity. When so much verbiage is wasted on any subject it engenders the suspicion that the reason for this wastage is a lack of knowledge or understanding of the subject. In the case of ulcer this is undoubtedly true. So much good research work has been done in regard to the pathology and etiology of ulcer and so well have the findings agreed with clinical experience, that it is surprising to hear even prominent surgeons and clinicians say that the cause is unknown. It is also peculiar that with the multiplicity of articles dealing with the well-known fact that in peptic ulcer there are almost invariably evidences of other inflammatory changes in stomach, duodenum, biliary tract, liver, pancreas, small and large intestine and appendix, it is taking both clinicians and surgeons so long to realize that in considering peptic ulcer as an entity and treating it as such they are not only illogical, but are definitely to blame for the poor results so generally reported.

PATHOLOGY

The pathology of peptic ulcer has not been given the attention it deserves. Lewis Gregory Cole has made a very valuable contribution to our knowledge in his studies of freshly excised ulcers, and parts of stomachs with ulcers, during the past five or six years, and his findings should be more generally made known. Cole divides ulcers into three groups, those of the body of the stomach, "corporic ulcers," those of the prepyloric region, "prepyloric or pyloric ulcers," and those of the first portion of the duodenum, "postpyloric ulcers" or "ulcers of the cap." He has shown that the ulcers are not the result of an erosion of the mucosa, but that they begin as areas of focal necrosis in the stomach or duodenal wall, and that they burst through in the line of least resistance, just as carbuncles or boils break through the skin. The intact mucosa can be seen curled under the edge of the ulcer. The size and depth of the ulcer depend on the site of the original area of focal necrosis and the degree of elasticity of the wall at this point. Thus an area of focal necrosis just under the mucosa breaks through rapidly and produces the small, rapidly healing submucosal ulcer, practically no more than a "canker sore," usually found in the prepyloric region, where there is little opportunity for its spread due

* Accepted for publication February 19, 1933.

to a relatively inelastic wall. An area of necrosis in the deeper layers, especially if in the loose areolar area along the lesser curvature of the stomach, will produce a deeper, wider ulcer. If the area is under the serosa, perforation is liable to result. All ulcers have a remarkable tendency to heal, as shown microscopically by evidences of a reparative process at the base of the ulcers, and as Cole has demonstrated in the living stomach by repeated serial roentgenograms, at short intervals, showing prepyloric ulcers disappearing in from a few days to two weeks and large lesser curvature ulcers in from a few weeks to two or three months. The healing of duodenal ulcers, because of the frequently persistent deformity resulting, is not as clearly demonstrable by radiography, but can be shown by reduced irritability of the duodenum on fluoroscopy and by disappearance from the duodenal contents of the ulcer base slough and blood. By demonstrating in removed stomachs the presence of multiple microscopic ulcer scars, often dozens in one stomach, Cole has arrived at the inevitable conclusion that each recurrent attack of ulcer symptoms is due to a new ulcer and that symptoms persisting or perhaps varying in intensity, are due to new ulcers developing before the older, partially healed ones have ceased to cause symptoms. Contrary to previously conceived notions, the finding of two or more ulcers in various stages of healing, is not at all unusual.

The *complications* of ulcers are easy to understand. *Perforation* has already been mentioned, and has for many years been considered not a

breaking through of an old ulcer, but a separate disease, the occurrence of such a severe ulcer that it immediately punched a hole through the whole stomach wall. Cole's explanation of this type of ulcer as due to an area of focal necrosis just under the serosa and breaking through in both directions, is simple and clear. If the point of perforation is opposite some organ, like liver or pancreas, or if it occurs into the lesser peritoneal sac, only a localized well-walled-off abscess area may result, but frequently the break occurs into the general peritoneal cavity, with resulting general peritonitis.

In the case of large or deep ulcers, especially where these are located at a narrow point, like pylorus or duodenum, although occasionally also in mid-lesser curvature, healing or external inflammatory reaction or both may result in so much cicatricial contraction as to cause obstruction to the onward passage of food—*pyloric stenosis* or *hour-glass constriction*. Acute inflammatory changes at such an area of narrowing or in a large ulcer may at times cause temporary complete stenosis, which may become partial or may disappear as the edema subsides.

Gross hemorrhage from ulcer is comparatively rare, and is due to the fact that the area of necrosis producing the ulcer happened to involve one of the larger vessels of the stomach wall. Hemorrhage will recur until the damage is repaired—usually by the organization of a thrombus in the injured vessel. If the eroded vessel is one running at right angles to the base of the ulcer (a terminal vessel) prompt retraction and cessation of hemorrhage occur, if lying longitudinally, with ero-

sion of its side wall, the hemorrhage will be persistent and often fatal. The vessels of some individuals seem less resistant to infection and these individuals tend to have hemorrhages with each recurrent ulcer. Superficial bleeding and serous exudation occur during part of the cycle of all ulcers.

The possibility of *carcinomatous degeneration* of gastric ulcers has in the past few years been relegated to its proper status. Studies conducted all over the world, and based on both clinical observation and pathological findings, have shown that carcinoma is no more apt to occur in the stomach of an ulcer patient than in the normal stomach, carcinoma having been shown to occur at the most in but four per cent of such cases. Cole, ten years ago, showed by statistics of cases seen by him that gastric carcinoma occurred more frequently in patients who had had operations for ulcer than in those treated medically. If we are to accept Cole's findings, which indicate spontaneous, rapid and complete healing of ulcers, it would give but little time for the development of malignant changes in any given active ulcer, leaving only the scar to act as a nidus

ETIOLOGY

The etiology of ulcer has been another moot point. The older theories considering trauma or irritation as etiologic factors were suddenly confronted, more than sixteen years ago, by Rosenow's demonstration of the etiologic relationship between focal infection and ulcer. Although Rosenow's laboratory experiments have not been universally confirmed by other observers, probably due to their using a

different technique, the clinical experience of those who have, like myself, made the removal of all possible focal infections the *sine qua non* in treatment, has been such as amply to substantiate the claims of such a relationship. Previous to Rosenow's experiments, Fenton B. Turck, showing that areas of focal necrosis could be produced in animals by intravenous injection of solutions of dead tissue (which contain minute amounts of the destructive shock toxin he has named cytolsin), in some instances produced typical indurated gastric ulcers in a few minutes. He concluded that this cytolsin was the causative factor. It seems only reasonable to assume that what may occur at the site of a focal infection, is an absorption of the cytolsin produced in the dead tissue resulting from the infection, and that the secondary focal necroses may be due more to electrochemical reactions of the tissues to this cytolsin than to actual initial migration of bacteria to the intact stomach wall. On the other hand, what relation anaphylaxis due to bacterial or tissue sensitization bears to the problem, has not as yet been satisfactorily determined. However, the results obtained in preventing recurrent ulcer when all possible infective foci have been removed, and the repeated recurrences in spite of any medical or surgical treatment where these foci have been neglected, affords clinical proof of the etiologic relationship between the foci and the ulcers.

PATHOLOGICAL PHYSIOLOGY

The *disturbed function* caused by the presence of an ulcer in stomach or duodenum is due primarily to irrita-

tion, and the results will vary with the degree of irritability of the patient's stomach, his general nervous irritability and the severity of the usually concomitant lesions in other parts of the gastrointestinal tract and its appendages. The most common result of irritation on the *motor function* of the stomach is an increase in the frequency and severity of the normal hunger contractions of the empty stomach, and at times the occurrence of such contractions before the stomach is entirely empty. Also, especially when an ulcer is near the pylorus or beyond it, there is frequently intermittent pylorospasm. In duodenal ulcer, and more particularly in lesions further down in the gastrointestinal tract, retroperistaltic waves (the retrostalsis described by Alvarez) may produce troublesome symptoms.

The effect of ulcer on the *secretory function* of the stomach is to cause an increased irritability of the gastric glands, with a resulting continued secretion, often reaching high levels of acidity, although at times there may be diminution or even an absence of hydrochloric acid in the gastric contents, due either to the exhausting effect of prolonged irritation or to chronic inflammatory changes, involving the gastric glands.

SYMPTOMATOLOGY

The *symptoms* of peptic ulcer are in most cases very characteristic. Epigastric pain, occurring after a longer or shorter interval after eating (usually from one-half to four hours after meals) and promptly relieved by the intake of any food or drink—the “hunger pain” of Moynihan—is practically

pathognomonic of ulcer. This pain is due to exaggeration of the normal hunger contractions of the empty stomach, and its severity and the time of its occurrence are, as mentioned above, dependent upon the irritability of the stomach and also upon the size and frequency of the meals taken, so that while some patients may get a severe pain within an hour after eating, others may feel no pain at all. The location of the ulcer has no effect upon the time pain will occur—gastric ulcers may cause pain three or four hours after meals, duodenal ulcers one or two hours after. If ulcers occurred alone, that is, if there were not, as there invariably is, an accompanying inflammatory reaction in other parts of the gastrointestinal tract, the symptoms would probably always be typical. These other conditions, the inflammations of the biliary tract, pancreas, appendix and colon, not only produce symptoms directly referable to themselves, but cause retrostaltic waves, producing pylorospasm and mild or severe reverse peristalsis in the stomach, resulting in epigastric distress or fulness immediately after meals, aerophagia, heartburn, sour eructations or actual regurgitation or vomiting. Some of them also cause more or less severe bowel symptoms. These other symptoms may be so prominent as to mask or modify the characteristic ulcer symptoms, thus making diagnosis by history alone very difficult. Loss of weight and strength, anemia, and various nervous manifestations are due to the individual patient's reaction to the symptoms—some starve themselves and grow thin and anemic, others overeat and gain weight rapidly. Some con-

sider that as long as food relieves them there is no cause for worry, others suspect cancer and become neurasthenics

The *symptoms of the complications* of ulcer are rather characteristic. In *gross hemorrhage*, hematemesis and melena, usually preceded by severe pain and fainting or collapse, are typical, although in the absence of hematemesis, the characteristic sticky, tarry stools, passed during the night may not be noticed, and the patient may describe only a diarrheal attack with vertigo or syncope

Perforation, ushered in by a terrific pain, not relieved by the food or alkali which the patient usually tries before the doctor arrives, and which is sooner or later followed by shock and the symptoms of peritoneal irritation, is a condition requiring immediate recognition so that prompt resort may be had to a life-saving operation

Pyloric stenosis and *hour-glass constriction* present the characteristic symptoms of delayed vomiting, that is, vomiting occurring at an interval after meals when all foods should normally have been expelled from the stomach. Patients with this complication who may previously have vomited soon after eating or at the time of occurrence of the ulcer pain, begin to vomit less frequently, often in the evening, and in the vomitus may be recognized food eaten two or three meals previously or even from the day before. Frequently there is a diminution of the ulcer pains, but a feeling of fulness in the upper abdomen and a more or less marked anorexia

The occurrence of *carcinomatous change* in an ulcer is accompanied by

an unusual loss of weight and strength, and an increasing pallor, associated either with symptoms similar to those previously complained of or a new train of rather indefinite dyspeptic symptoms, with anorexia. Often gross hemorrhage may be the first symptom of a carcinoma

DIAGNOSIS

The diagnosis of peptic ulcer is usually made by means of three characteristic findings—the history, examination of gastric and duodenal contents by the fractional method and the roentgen ray examination

1. The *history* is often of the greatest help in diagnosis. Recurrent attacks of typical hunger pain, that is, pain occurring after an interval of from one-half to three or four hours after meals and relieved by the intake of food, drink or alkali, was long ago described by Moynihan as pathognomonic of ulcer, and in my experience it is extremely uncommon not to be able to demonstrate an ulcer when this symptom is present. The pain is most commonly located in the epigastrium, but at times may be located in the gall-bladder or appendix regions, in either inguinal region, the precordium or the back. Retrostaltic symptoms, as described above, are not characteristic of ulcer, but are more frequently due to the other co-existent gastrointestinal lesions. Vomiting, occurring immediately after meals or at the time of the pain, is one of these retrostaltic symptoms, but if it is of the “delayed” type, is characteristic of stenosis. The symptoms of other complications have been mentioned. A first attack of ulcer symptoms, especially in a patient

of carcinoma age and if continuing over a period of a few months, may be due to a carcinomatous ulcer

2 *Careful fractional gastric analysis*, preceded by examination of the fasting residue after a duration meal of rice and raisins, is of great help in diagnosis. Three findings are studied namely, those relating to motility, to secretion and to admixtures

A *Motility* an overnight residue of gross rice and raisins indicates pyloric stenosis, the degree of which may be determined by the rapidity with which the stomach can expel the test meal subsequently given. In the absence of an overnight residue, delayed expulsion of the test meal indicates marked pylorospasm and the probable presence of a lesion near the pylorus, but not obstructing it

B *Secretion* is indicated by the curve of acidity following ingestion of a test meal or the intramuscular injection of histamine dihydrochloride. In gastric ulcer this curve is not of value there may be a normal curve, there may be no secretion of acid at all or there may be a continued secretion. In pyloric and post-pyloric ulcers we find that a continued secretion, i.e., secretion continuing beyond the normal period of secretory reaction to a stimulus, and often reaching great heights of acidity, is the rule, although here, also, achylia is found at times, especially in long-continued cases

C *Admixtures* The presence in the gastric contents of small, more or less dried particles of blood, with adherent detritus coming from the base of an ulcer, is a valuable finding, but

is difficult to differentiate from blood due to trauma in swallowing the tube. It is, however, of some value in confirming an x-ray finding of gastric ulcer. Where no blood is found in the gastric contents until the normal reflux of bile stained duodenal contents during the second hour after the test meal, and the particles just described are then encountered, we have a very characteristic finding of duodenal ulcer. Gastric analysis is of little or no value in differentiating between gastric ulcer and even well-advanced carcinoma, although the continuous presence of blood is suspicious of malignancy. In rare instances pieces of carcinoma tissue may be aspirated and recognized microscopically. In carcinoma associated with pyloric stenosis, a fasting residue containing no free hydrochloric acid and in which Boas-Oppler bacilli and lactic acid are present, is found in a large proportion of cases

3 *The roentgen ray diagnosis of ulcer* is of great importance. The characteristic findings on a radiographic film are the presence of a *defect*, which represents the displacement of the ingested barium mixture by the area of induration about an ulcer, and a *protrusion* (niche) which represents the crater of the ulcer. In the case of the large (corporic) ulcers which nearly always occur at some point along the lesser curvature, the protrusion may be large (up to 5 cm in diameter) and the defect extensive. In the case of small prepyloric ulcers the protrusion may be very small, the defect barely noticeable. In the duodenal cap the crater is not as frequently seen, but the induration causes persistent deformities which are characteristic

Fluoroscopic examination is subject to grave error in that more than fifty per cent of even large corporic ulcers are not recognized and the small prepyloric ulcers are rarely seen, although the deformity and irritability of the duodenum make ulcers of the cap easily recognizable by this method.

A persistent deep incisure on the greater curvature often indicates the presence of a posterior wall ulcer. In pyloric stenosis due to ulcer a large atonic stomach with a smooth outline at the point of obstruction is the rule, the ulcer crater being less frequently seen than in hour-glass constriction. Where perforation is suspected the barium meal is contraindicated, but a "flat plate" of the abdomen (a safe procedure) will often show an accumulation of gas above the dome of the liver. After a gross hemorrhage, roentgen examination should be deferred for at least two weeks after cessation of the hemorrhage.

Where the defect or crater shows an irregular outline or where there is not a definite decrease in size of a gastric defect in a period of a few weeks, carcinomatous ulcer must be suspected and exploration resorted to in order to clinch the diagnosis.

TREATMENT

The treatment of peptic ulcer resolves itself into three distinct procedures: the local treatment of the ulcer by mechanical means, the removal of the cause and the care of the complications.

1. *The local treatment*, as in the case of an ulcer in any part of the body, consists in putting the ulcer area at rest and in keeping it soothed so as to permit of healing. The stomach is

never entirely at rest, but it is most active, even to the state of tetanic contractions, when empty. The normal hunger contractions are exaggerated in the presence of an ulcer and can best be relieved and prevented by keeping the stomach full of soothing food. The food should be sufficiently nutritious to permit of the body carrying on the healing process effectively, and where the patient is undernourished, should add to his weight. It should, like any diet, contain the proper balance of essential ingredients, and have an adequate vitamin content. While we do not feel that acidity plays any particular part in the production or persistence of an ulcer, combination with free acid and avoidance of over-stimulation of gastric juice are desirable. Daily bowel evacuation, while not essential, is encouraged by the frequent feedings, the drinking of sufficient water, the addition of yeast to the diet and the administration of mineral oil. General bodily rest is to be encouraged, although rest in bed is very rarely necessary. A suitable diet would be as follows.

Breakfast Milk, 8 ounces, with cream if desired
 Cereal, 5 ounces, with milk or cream
 Egg, 1 soft boiled or poached
 Bread or toast with butter
 Fruit juice (at end of meal)
 Midmorning. Milk, 8 ounces (cream $\frac{1}{2}$ ounce, lactose, $\frac{1}{2}$ ounce, or cocoa may be added if desirable)
 Always with crackers, toast, bread or cake
 Luncheon: Milk 8 ounces
 Baked or mashed potato or plain spaghetti
 Egg, 1 soft boiled or poached, or cream cheese
 Bread and butter
 Pudding, custard, gelatin or ice cream

Midafternoon Same as midmorning
 Supper Same as breakfast or luncheon
 At bedtime and during night (every 2½ hours, if awake) Same as at midmorning
 Olive oil, ½ ounce three times a day before meals
 Liquid petrolatum, ½ ounce at bedtime
 Water, 6 or 8 glasses per day

2. *The removal of the cause*, as discussed under the head of etiology, consists in the systematic and thorough eradication of all infective foci. Half-hearted removal of an abscessed tooth or infected tonsils is rarely sufficient. It is necessary to search for and remove all devitalized or impacted teeth, and root fragments, fillings or cysts remaining after extractions. Moderate pyorrhea may be kept under control by means of frequent scalings, but the ultimate cure of definite pyorrhea is extraction of the diseased teeth. Infected tonsils or tonsil remnants must be extirpated, and nasal, pharyngeal, sinus and ear infections must be eliminated. Such common sites of focal infection as the male and female genital tracts, the rectum and all other parts of the body must be expertly examined and thoroughly cleaned up. Failure to remove all infective foci, even though diet is strictly adhered to, will eventually result in recurrence of ulcer, although an exacerbation is undoubtedly hastened by dietetic indiscretions or nervous or physical strain. With the appearance of a new ulcer, complete check-up for neglected, recurrent or new foci must at once be instituted, and in our experience such foci are always found.

3. *The treatment of the complications* of ulcer includes the treatment of perforation, stenosis and hemorrhage.

Perforation requires operation as soon as the patient has rallied from his shock (usually within the first two or three hours) the additional shock of too early operation often being the cause of unnecessary mortality. Operation during the first six to twelve hours results in the lowest risk. If not operated upon after twenty-four hours most patients die. Closure of the perforation by suture and covering with omentum is usually the best procedure, additional operative interference, on account of the increased risk involved, being carried out only where an obstruction is present.

Stenosis, whether due to hour-glass constriction or to pyloric or post-pyloric ulcer, also requires operation, but where the patient is depleted and dehydrated from prolonged vomiting a few days or even a week of preparation is worth while, reducing mortality and shortening convalescence. Such preparation would consist of frequent, small, liquid, concentrated feedings, subcutaneous and intravenous administration of chlorides and glucose and transfusions. Early feedings after operation and a proper dietetic régime afterwards, insure a good result. In the present article a discussion of the operative procedures is not desirable, but suffice it to say that the more simple the operation, the better it will be for the patient.

Gross hemorrhage is accompanied by shock and dehydration and is followed by a more or less severe anemia. Its treatment, which I have discussed in detail in a previous communication* involves the following principles

*The treatment of gastric hemorrhage, Jr. Am Med Assoc, 1927, lxxxix, 1397-1400

1 The promotion of blood clotting in the bleeding vessel; 2 The preservation of the clot when formed; 3 Treatment of shock; 4 Keeping the patient in the best possible general condition; and 5, Determining the nature of the lesion from which the hemorrhage originated. The first indication is absolute rest in bed, enforced by definite doses of morphine. This treatment combats shock and helps to check bleeding. Even though blood coagulation tests show normal findings, it is often best to use some form of medication to promote coagulation—horse serum, fresh or dried, thromboplastin preparations or whole human blood. A sudden increase in blood volume or blood pressure might tend to dislodge an early and unorganized thrombus, so that intravenous, subcutaneous or rectal fluids, and stimulants tending to raise blood pressure, should be avoided. In the presence of air hunger, transfusion of blood should be resorted to, but a small amount (250 cc or less) will usually be sufficient. After ten days, one or more larger transfusions will materially shorten the period of convalescence. Feedings are instituted at once in order to prevent the sometimes violent hunger contractions, which so often are the cause of recurrent hemorrhage. The food should be soothing, should promote coagulation of blood at the bleeding point, should combine readily with gastric juice (to prevent digestion of the thrombus) and should not over-stimu-

late gastric secretion. Such a substance is gelatin, which is used in solution and to which later are added gruel and milk mixtures, cereals, puddings, soft eggs, etc., until a regular ulcer diet is reached at the eighth or ninth day after treatment. Complete gastrointestinal study is not begun until nearly two weeks after the hemorrhage. Ice should be avoided, internally because it produces hyperemia of the gastric wall, externally because it adds to shock.

SUMMARY

1. So-called peptic ulcers are produced by the breaking down of areas of focal necrosis in the stomach wall, at varying depths below the mucosa.

2. They are the result of focal infection, the mechanism of their production being probably not direct infection, but some allergic or electrochemical reaction in the tissues involved.

3. They tend to heal spontaneously, each attack of ulcer symptoms being due to the development of a new ulcer.

4. The symptoms of ulcer are due to exaggerated hunger contractions and to retrostalsis.

5. The diagnosis of ulcer depends on history, roentgen ray and fractional gastric analysis.

6. The treatment of uncomplicated ulcer consists of diet and the thorough eradication of all focal infections.

7. Operative treatment is reserved for the complications of ulcer.

Malignant Melanoma with Delayed Metastatic Growths*

By DWIGHT L. WILBUR, M.D., and HOWARD R. HARTMAN, M.D., F.A.C.P.,
Division of Medicine, The Mayo Clinic, Rochester, Minnesota

MALIGNANT melanoma, frequently termed melanosarcoma or melano-epithelioma, is one of the most malignant tumors encountered in man. In some instances, however, the body seems to possess unusual resistance to metastasis from these tumors and it may be years after the appearance or removal of the primary growth before sudden, rapid and overwhelming metastasis occurs. This type of growth should, therefore, lend itself well to the study of the mechanisms of metastasis of tumors and bodily resistance to tumor growth, were it possible, with present knowledge, to approach such a study. The established observations of the delay in metastasis of these tumors are exceedingly important, not only in the diagnosis of this rare disease, but also because the prognosis may not be completely favorable in any case regardless of the time elapsed after excision of the primary growth. The present study has been undertaken with the view of presenting the histories of selected cases to reemphasize these facts, and to record observations on the life history of the disease. There are few

conditions apparently so readily cured in certain cases by simple excision as is melano-epithelioma, only to recur many years later in a rapidly fatal form following an interval of perfect health.

Malignant melanomas have been found to arise in several different organs of the body. The most common site is the pigmented mole of the skin and following this, in order, the pigmented areas of the eye, the anus and the suprarenal glands; such tumors have been reported as arising in the meninges, rectum, ovary, gastro-intestinal tract, gallbladder and other organs. There is considerable dispute as to the cellular origin of this type of tumor. It was formerly believed to arise chiefly from mesoblastic tissue and this, with the spindle type of cell which is commonly observed, led to the term melanosarcoma, which is still used. Certain observers believe it arises from the melanin-bearing chromatophores which are so widely distributed in the animal kingdom, although more recent interpretations place its origin among the epithelial cell group. Although the latter is the most commonly accepted view Ewing has recently accepted the work of Mason which would indicate that these

*Submitted for publication February 20, 1931

tumors have their origin in nevus cells derived from and belonging to the end organs of peripheral sensory nerves. The cell form varies from spindle to round and, although most of these tumors are pigmented with melanin, occasionally nonpigmented melanoma is encountered.

The spread of these tumors may occur in three ways: by direct extension, by lymphatic vessels, and by the blood stream. Death within a month of onset has been recorded, but the usual duration of life, according to Coley and Hoguet, is two to three years. However, in certain cases in which there is definite resistance to metastasis, recurrence may not appear for as long as ten to thirty years after removal of the primary growth. The various modes of extension and the various types of metastatic growths will be illustrated by the case histories presented. Cases have been selected in which metastasis occurred after a period of at least five years after excision of the primary growth.

In each of the following three cases the primary growth occurred in a pigmented nevus of the skin and led to metastasis which did not become prominent until years later. At the time of examination these cases did not present the widespread metastasis which is the terminal stage of the disease.

CASE 1 A woman aged 43 years, registered at The Mayo Clinic in May, 1919, because of a tumor of the right thigh. Ten years prior to registration, a mole on the right thigh was accidentally irritated, following which it bled and later enlarged. Excision of the nevus was carried out at that time and the patient remained well until 1914, a year previous to coming to the clinic, when a brown area developed in the

scar and gradually increased in size. Six months later she noticed swollen nodes in the right groin. Shortly thereafter anorexia and weakness began.

In the region of the scar there was a pinkish flattened area 4 by 2.5 cm, and in the inguinal region were many enlarged lymph nodes. Biopsy of these nodes showed melano-epithelioma. The patient died after she returned home.

CASE 2 A woman, aged 48 years, came to the clinic in May, 1928, because of weakness of four years' duration. For fifteen years she had had a raised pigmented nevus on the left leg. Shortly after the appearance of the nevus it was cauterized, without recurrence, but six years later a tumor developed in the left groin, which remained unchanged for several years. Four years prior to registration the patient had severe menstrual hemorrhage at the time of the menopause and following this the tumor in the left groin continued to increase in size.

General examination was essentially negative save for a fixed, firm tumor, 3 by 5 cm, on the anteromesial surface of the left thigh. The patient refused biopsy and returned home. A diagnosis was made of metastatic melano-epithelioma of the left groin. The further course is unknown.

CASE 3 A woman, aged 61 years, registered at the clinic in April, 1917, because of a growth in the left temporal region, which had started as a small lump one year previously. It grew rapidly and was cauterized a month later, but the ulcer which developed on the lump failed to heal and increased in size. Tincture of iodine had been applied locally on several occasions. The growth had been enlarging rapidly and was rather painful.

On careful questioning the patient recalled that twelve or thirteen years previously she had had a brown mole burned off the cheek just below the site of the present growth, which was a raised, rather firm growth 5 cm in diameter, covered with blood crusts on the upper portion of the left cheek. Just below it was a similar area 2.5 cm in diameter. There were no palpable cervical nodes surrounding it. The pigmented

area was excised. The pathologic diagnosis was melano-epithelioma.

The patient returned in September, 1917, at which time there was a small ulcer 1.5 cm in diameter on the face, but no clinical or microscopic evidence of recurrence. She returned again in November, 1917, stating that her health had been good until six days previously, when she noted drooling of saliva from the left side of the mouth. Left hemiplegia and aphasia with some frontal headache and delirium, and then coma, rapidly developed. Death occurred two days later.

At necropsy there was a large healed scarred area on the left upper malar region with atrophy and scarring of the skin. There were several areas of metastatic growth in the lungs, and bronchopneumonia. Excessive hemorrhage had occurred in the left internal capsule of the brain, and into all the ventricles, with thrombosis of the left lateral sinus. Although it could not be definitely determined, there was some suspicion that a metastatic melano-epitheliomatous growth was present.

It should be pointed out that following excision of the primary growth local recurrence may or may not take place, and that if local recurrence is present it may occur immediately following excision and remain stationary for years, or it may not be present until years later at the time of widespread metastasis.

The four cases of the second group are illustrative of the presence of distant metastasis in the absence of local recurrence in the skin.

CASE 4 A woman, aged 42 years, came to the clinic in June, 1926, because of a lump in the right groin, of four months' duration. In 1920 she first noted rapid growth of a pigmented mole on the calf of the right leg. The following year, the mole, which had become 2.5 cm in diameter, was excised (elsewhere) and a diagnosis of sarcoma made. Because of this, the popliteal area was dissected out a few days later. She had no further trouble until February,

1926, when pain developed and a lump was noted in the right groin. There was some question as to whether the lump had grown during the succeeding months.

General examination disclosed a large irregular fixed mass in the right groin which seemed to extend into the right side of the pelvis, where a large firm mass could be palpated. The scars of the previous operation appeared normal. A diagnosis was made of metastatic melano-epithelioma, and the patient returned home following treatment by irradiation. The outcome is unknown.

CASE 5 A woman, aged 53 years, came to the clinic in March, 1927, because of frontal headaches of two months' duration. The pains radiated to the occipital region, and they were persistent and intense. Nausea and vomiting, and vomiting unaccompanied by nausea, occurred. The patient was drowsy and lethargic, with diminished vision and drooping of the left side of the face. Ten years previously a mole had been removed from the left side of the face, it had recurred several times and was removed each time. Two months preceding registration a small black tumor behind the left ear had been observed.

General examination disclosed moderate obesity, lethargy, nystagmus and paralysis of the left side of the face. There was a firm tumor, 1.5 by 1 cm, below the left ear. It was somewhat tender, and movable. Ophthalmologic studies revealed bilateral choked disks of 4 to 5 diopters each, with hemorrhages and exudates in the retina. The roentgenogram of the thorax was negative. Biopsy of the tumor below the left ear disclosed melano-epithelioma, and a diagnosis was made of brain tumor (metastatic) and melano-epithelioma in the left temporal region. The patient returned home. Further data as to the outcome are not available.

Case 5 presents several interesting points. First, it illustrates the persistence of the growth in spite of continued cauterization and yet the long delay before the resistance of the patient was lowered or the virulence of

the tumor raised to the point of metastasis. Second, it illustrates the advantage of biopsy of a suspicious cervical or cranial node in the presence of an obvious intracranial neoplasm, for it not only clinched the diagnosis in this case, but it saved the patient a needless exploratory operation as well. Third, it is an instance of the rare case in which the presenting symptom of the metastatic growth is that of an intracranial lesion, and it is probably the type of case in which intracranial metastasis will be fatal before widespread metastasis is evident.

CASE 6 A man, aged 35 years, first came to the clinic in May, 1929, because of migraine and chronic nervous exhaustion. He returned in March, 1930, because of numerous subcutaneous lumps which had appeared in October, 1929. There had been slight swelling of the right testis for a few months preceding this. About twelve firm, painless subcutaneous nodules were scattered over the torso, all of which had progressively increased in size. The patient had grown increasingly pale, lost 10 pounds in weight and had a dry hacking cough. Malignant melanoma was reported following biopsy of one of the tumors (elsewhere). There was a history also of removal of a nevus from the right calf in 1923 or 1924.

On general examination fatigue was apparent. Numerous subcutaneous dark nodules, 0.5 to 2 cm in diameter, were noted. On the inner side of the right calf there was a clean scar where the mole had been excised. The abdominal examination was negative, as was the roentgenogram of the thorax. A diagnosis was made of malignant melanoma with metastasis. The patient returned home, where he died three months later of generalized metastasis.

Among the interesting features of this case is the absence of evident local or regional recurrence of the melanoma ten years previously. This is unusual considering the fact that the

lesion originated in the skin, which practically always gives evidence of local recurrence or of metastasis to the regional lymph nodes. The only clinical evidence of metastasis in this instance was the subcutaneous nodes, and it should be mentioned that this patient had been subjected to careful examination ten months previously, at which time the nodes were absent.

CASE 7 A man, aged 33 years, first came to the clinic in 1920, at which time a pigmented nevus on the skin of the left deltoid area was excised. There had been some recent increase in the size of the nevus prior to its removal. Thereafter the patient continued in his usual good health save for occasional attacks of vague abdominal pains, the exact nature of which could not be determined. In June, 1930, he returned to the clinic complaining of pains of two months' duration in the lower part of the abdomen. The pains occurred several hours after meals, and were associated with backache, fatigue, and loss of 15 pounds in weight.

General examination was essentially negative, but laboratory tests revealed secondary anemia (10.2 gm hemoglobin for each 100 cc), and occult blood in the stools. Roentgenographic examination of the stomach disclosed a small polyp. At abdominal exploration multiple malignant polyps were found scattered throughout the small intestine, one of which had produced intussusception of the lower part of the ileum. The patient was unable to withstand the operation and at necropsy widespread metastasis of malignant melanoma was observed. Six cauliflower-like pedunculated and sessile growths were found in the right auricle of the heart, the largest 2.5 cm and the smallest 0.7 cm in diameter. In the lungs were numerous firm nodules 2 mm to 2 cm in diameter. Similar metastatic nodules were observed in the liver and spleen (one nodule). The stomach was dilated and presented a polyp on the posterior wall 7 cm from the pylorus. There were many small masses scattered throughout the duodenum, jejunum, and ileum, the largest of which measured 5 by

3 by 15 cm They occurred as sessile, pedunculated or ulcerating areas, greater in number high in the small bowel The colon and rectum were free of metastasis Microscopic study revealed pigmented epithelial tumor cells with both adenomatous and epitheliomatous formation, and the diagnosis was made of malignant melanomatosis with multiple metastasis

The remarkable features of this case were the misleading symptoms which the patient presented The gastro-intestinal symptoms were outstanding and there was no suggestion of malignant disease until the time of operation when the carcinomatous polyps were discovered It was the presence of intussusception which led to surgical interference A similar case of metastatic malignant melanoma and intussusception of the small intestine has been reported by Maxwell The presence of widespread metastasis to the heart, lungs, liver, spleen and stomach and small bowel revealed the hopelessness of the condition and yet it had been ten years since the excision of the primary growth

The last group, which comprises three cases in which the eye was the site of the primary melanomatous growth, is perhaps the most interesting and clinically the most startling of the series

CASE 8 A man, aged 43 years, came to the clinic in June, 1930, because of weakness and an abdominal mass of six months' duration Seven months previously he had had a heavy cold with slight fever and thereafter he continued to have bouts of mild fever, malaise, pains in the joints and weakness Four months previously he first noted a painless, somewhat movable mass in the right upper abdominal quadrant which later enlarged and moved toward the median line Because of a sense of fullness the appetite failed, although there was no indigestion or

jaundice Further questioning brought out the fact that in 1916, fourteen years prior to registration, the left eye had been removed because of "acute glaucoma following detachment of the retina" and in 1929 he noted the appearance of dark colored nodules on the right wall of the thorax anteriorly, at the base of the neck, in the left axilla, the groin, and near the spine These areas were painless, movable, and had not changed in size during the last year

The patient was slightly emaciated and numerous firm movable black nodules were noted The abdomen presented a hard nodular mass with a definite border coming down to the umbilicus in the right upper quadrant, and the spleen was palpable A roentgenogram of the thorax disclosed an area of increased density in the right lower lobe, probably metastatic Tests of hepatic function disclosed dye retention graded 4, indicating marked hepatic disease Biopsy of one of the inguinal nodes was reported as melano-epithelioma The diagnosis was made of melano-epithelioma involving the liver and abdominal lymph nodes The patient returned home, where he died two months later

CASE 9 A man, aged 55 years, came to the clinic May 12, 1930, because of pain in the right upper quadrant of the abdomen and loss of weight He had been in his usual good health until six or eight months before admission, at which time illness which was called influenza by his physicians developed, with increasing weakness and gas on the stomach Although the respiratory infection rapidly cleared up, the feeling of abdominal distention became more pronounced and soon moderately severe continuous pain developed, starting in the epigastrium and passing to the umbilicus Two months before admission he had first noted the appearance of painless, subcutaneous lumps over the sternum and left shoulder About this same time the gastro-intestinal symptoms improved, but six weeks before admission a pressing pain developed beneath the right costal margin which bothered him, especially at night He had lost 20 pounds in weight. In general he felt well, with the exception of some weakness and slight cough with mucoid expectoration In 1920, his right eye had been enucleated because of a tumor

Biopsy of one of the subcutaneous nodules removed elsewhere had been diagnosed sarcoma

The patient was slightly emaciated. The orbit from which the right eye had been enucleated did not give evidence of recurrence of growth. There were numerous, scattered, firm, freely movable, painless, subcutaneous nodules over the scalp and thorax. The axillary and cervical lymph nodes were large and there was a large firm irregular mass, presumably the liver, in the right upper quadrant of the abdomen. A few râles were noted at the bases of the lungs. Laboratory studies showed mild secondary anemia with 126 gm of hemoglobin for each 100 c.c., and the roentgenogram of the thorax disclosed multiple metastatic granules. A diagnosis of multiple metastatic tumors throughout the body was made, the source undoubtedly being the tumor of the eye enucleated ten years previously.

CASE 10. A man, aged 53 years, came to the clinic November 18, 1930, because of stomach trouble which he had had for twenty years. The distress was a typical ulcer type of dyspepsia which became pronounced two months before admission. During this time he had suffered from constant epigastric pain which radiated to the right upper and lower abdominal quadrants and up into both sides of the thorax. Relief from food or alkalis was incomplete. There were no other gastro-intestinal symptoms and he had not lost weight. In 1920 the right eye had been enucleated on account of sarcoma of the eyeball.

The patient was emaciated. The tissues of the right orbit appeared normal. A small firm, freely movable, subcutaneous nodule had been present over the third thoracic vertebra for a year. A large, firm, irregular, scarcely movable and tender mass was palpated in the right upper abdominal quadrant; presumably it was the liver. Laboratory examination disclosed slight secondary anemia, the hemoglobin was 135 gm. Roentgenograms of the stomach disclosed an extrinsic mass. A diagnosis of melanoma of the liver was made.

The points of similarity of these three cases are quite remarkable. The

patients had all undergone enucleation of the eyeball for tumor (in the first case "detachment of the retina for glaucoma") ten or more years previously, apparently with success and with good health through the intervening period. In each case the presenting complaint was of epigastric pain focusing the attention on the abdomen, and on examination the liver was found to be large, firm, and irregular, obviously the seat of malignant disease. Each patient also presented one or more subcutaneous nodules, although there was no evidence of local recurrence within the orbit or of regional metastasis. The essential data of these cases are compiled in the tabulation (page 210).

COMMENT

Malignant melanomas arising within the pigmented nevus comprise the majority of such tumors. The various modes of metastasis have been illustrated in the case reports. There may be local recurrence of the growth following excision, metastatic involvement of the regional lymph nodes, or of neighboring organs, or widespread metastasis throughout the body.

The varying clinical picture observed in the localization of metastasis may be explained in four different ways: (1) it may depend on the occurrence of metastasis by way of the lymphatics, in which case transportation of cells by superficial lymphatics would lead to metastasis in the regional nodes, while transportation by deep lymphatics may lead to metastasis in more distant lymph nodes or even widespread dissemination through the thoracic duct and blood stream; (2) the metastasis may be by the hemato-

genous route, in which case widespread metastasis is more probable; (3) the clinical picture may depend on the stage, early or late, in which the disease is observed, and (4) the quality and quantity of metastasizing tumor cells may be the determining factors, as pointed out by Armstrong and Oertel, since with a small number of cells the localization depends on qualitative selection of suitable organs for extension of metastasis, while with large quantities of cells this qualitative restriction is overcome and widespread overwhelming metastasis occurs. At present, there is no method of predicting which means of dissemination will be followed by a melanotic tumor in a given case.

There is just as much variability in the time elapsing between the occurrence of malignant changes in the nevus and the development of disseminated metastasis as there is in the selectivity of routes of dissemination. The occurrence of these two factors is so well established that they need no further defense.

In each case cited there was growth of the pigmented nevus just prior to excision or cauterization. Such a change therefore immediately justifies a guarded prognosis as to the occurrence of metastasis following removal of a growing nevus. The impression should not be obtained that dissemination is bound to occur once visible proliferation of the original nevus has begun, but the point to be emphasized is that one can never be absolutely certain, even after many years, that widespread metastasis will not occur. It would seem that the treatment of choice in such cases would be not only wide excision of the offending nevus

but of the regional lymph nodes and intervening lymphatic vessels as well, as emphasized by Handley. The occurrence of bleeding, ulceration or crusting of a pigmented nevus should always be taken as a serious warning and be followed by immediate excision, as already mentioned.

Malignant melanomas arising within the eye comprise about one third of the whole group of malignant melanomas and are generally regarded as taking origin in the choroid, ciliary process, iris and conjunctiva. The more recent work, however, seems to indicate that they arise in the pigmented layer of the retina. This confusion is the result chiefly of failure to observe early cases histologically. The mode of extension from the eye, according to Dawson, may be in three directions: (1) by direct extension, (2) by lymphatics to the cranium, or more rarely to the cervical nodes, and (3) by the blood stream, chiefly to the liver. Among the numerable cases in the literature in which metastasis has been delayed for many years following excision of the primary growth are those of Wilder, thirty-two years; Schilling, twenty years, Lawbaugh, seventeen years, Fisher and Box, fourteen years, and Hutchinson, Lilley, and Dobbertin, ten years. The syndrome is so well established that when one is confronted by a patient with a glass eye and a large abdomen or liver the suspicion should immediately be aroused that a malignant melanoma has metastasized, regardless of the number of years since enucleation of the globe. Malignant tumors within the eye are nearly always primary for, as Cordes and Horner have pointed out, metastatic tumors to the eye are

rare (seventy cases of metastatic carcinoma to the eye are reported in the literature, chiefly from the breast), and there are only four recorded cases of metastatic melanoma of the skin with metastasis to the eye. Such metastasis usually occurs in the uveal tract. Metastasis from one eye to the other seldom occurs; consequently a malignant melanoma of the eye can be regarded quite safely as primary in that organ. Such statements as those of Karsner that "the pigmented choroid tumor is extremely malignant and secondary foci or metastasis develops very early" cannot be accepted for all cases, as has been illustrated.

Malignant melanomas arising in other organs have not been cited in the present study because delay in metastasis from such tumors has not been observed, chiefly because the primary tumor is not viewed as readily as are those in the eye or skin. Although melanomas conceivably may arise wherever melanin-bearing cells occur, their occurrence primarily in the stomach or small intestine is questionable. The usual involvement of the liver and occasionally of the gastro-intestinal tract in the absence of a known primary growth has led to the belief that the primary tumor may be in these organs, particularly if the patient's history is unknown. The secondary tumor in the small intestine may have all the appearances of a primary growth, as occurred in one of the foregoing cases, and also in the case cited by Saphir. Saphir's experience led him to conclude: "Reports of primary melanotic tumors of the intestine should be regarded with suspicion."

Delay of metastasis is probably more correctly called delayed metastatic

growth, for it is logical that the metastasis, or at least the dissemination of tumor cells, must take place before or during the successful operative removal of the primary growth. The mechanism of this phenomenon of delayed growth is not certain.

It is not difficult to understand the entrance into, and transportation of tumor cells by either the blood stream or lymph stream in the development of metastasis. Similar phenomena probably occur in the development of metastatic abscesses, foci of infection, or orchitis in mumps, and possibly also the so-called calcium metastasis in which this inorganic salt is carried from the bones to the lungs, stomach and kidneys. The development and growth of metastatic cells is so commonly observed that little attention is paid to the mechanisms by which they occur. It is this part of the development of metastasis which is so little understood. In this consideration Oertel stated "It must be appreciated that transportation of tumor cells and even arrest of tumor plugs are not identical with metastasis, for the conception of metastasis requires further a participation of the local tissues in the growth of cells to a tumor by furnishing the tumor cells with a vascularized stroma. . . The local susceptibility determines more than transportation of tumor cells the development of the metastasis."

The delay of metastasis must depend, therefore, not on any altered transportation of the tumor cells but on their delay in growth, and that this delay in growth may be for many years is a remarkable phenomenon. The actual transportation and distribution of the tumor cells must be very wide-

spread since the liver is so frequently involved secondarily. This would necessitate the passage of the cells through at least one or more capillary beds, probably two, that is, the pulmonary and portal.

The inhibition of growth of the transported tumor cells in certain organs over many years is evidence, perhaps, of failure of adequate powers of resistance of the organ or of the presence of an aggressive "formative irritant" (Oertel) in the tumor cells in their relation to the affected organ. Cohnheim stated "Only when and where tissues are lowered in their physiological metabolism by age, atrophy and inflammation will metastasis be possible." This would indicate that the resistance of the organ must be lowered before actual metastatic growth occurs and this may in fact be due, as Symmers put it, to some alteration in the "equilibrium of function in the cell (tumor) itself" or possibly to the occurrence of trauma. When such a point is reached the organ is stimulated to the development of a "vascularized stroma" and the growth of the cell deposit occurs with fulfillment of the conception of metastasis. Such hypothetical considerations will be replaced in time by more accurate facts as our knowledge increases, but for the present we are uncertain what influences suddenly fan the coals to flames when the metastatic growths appear.

It should not be supposed that malignant melanomas comprise the only group of tumors in which delay of metastasis occurs. Other types of tumor may show the same phenomenon and because of this the "three-year or five-year cures" of malignant tumors can not always be accepted. This is par-

ticularly well illustrated by such a case as that reported by Stacy and Vanzant in which an apparently inoperable carcinoma of the uterine cervix treated by radium seemed to heal and yet seven years later at necropsy metastasis in neighboring lymph nodes showed evidence of apparently recent, active carcinomatous growth.

There are several other points of clinical interest. The primary growth in malignant melanoma, unless it is within the eye or the brain, is not usually of great clinical significance. It is the widespread dissemination which usually destroys life, and death does not occur until widespread metastasis has occurred. This property applies to few other known tumors. McWhorter and Cloud found that in the nine cases of malignant melanoma which came to necropsy at the Bellevue Hospital widespread metastasis was present in each case and the liver was usually affected. Metastasis to the liver is present in the end stage in almost every case of this disease. This is an interesting phenomenon which cannot be explained at the present time except by the lowered resistance of the liver. Lymph nodes are not necessarily involved in every case.

The subcutaneous nodules observed as metastases may readily be misinterpreted as sebaceous cysts, as actually happened in one of the cases reported here.

From the medicolegal standpoint the delay of metastasis of these tumors may be very important, for the removal of the primary growth may occur in a period either covered or not covered by clauses in insurance policies or other legal papers, whereas the metastatic growth may occur years la-

SUMMARY OF CASES

Case	Sex and Age	Primary Growth		Site of Metastasis	Appearance of Metastasis, years	Diagnosis	Chief Complaint	Outcome
		Site	Treatment					
1	11F	Mole on anterior surface of thigh	Excision	In scar and inguinal nodes	8.5	Biopsy of nodes	Tumor of thigh for six months	Died; time?
2	12F	Mole on calf of right leg	Excision	Inguinal nodes and pelvis	5	Biopsy of original tumor	Lump in right groin for four months	Unknown
3	18F	Mole on left thigh	Cautery	Anterior surface of left thigh	6	Clinical history and examination	Weakness for four years	Unknown
4	61F	Skin of cheek	Cauterization	Local recurrence and lungs and intracranial sinuses	12	Postmortem examination	Lump on face for one year	Died seven months after excision
5	53F	Mole on left side of face	Removed; several recurrences	Brain and behind left ear	10	Biopsy of mass on left ear	Headaches for two months	Unknown
6	35M	Mole on right calf	Excision	Subcutaneously, right tonsil	6	Biopsy of subcutaneous nodes	Subcutaneous nodes for five months	Died nine months after secondary metastasis
7	33M	Nevus on left arm	Excision	Heart; spleen, stomach, intestines, mesentery, lymph nodes; liver and lungs	10	Postmortem examination	Weakness and lower abdominal pain for two months	Died after operation
8	13M	Eye	Enucleation	Liver and subcutaneously	13	Biopsy of inguinal node	Weakness and mass in abdomen for six months	Died two months later
9	53M	Eye	Enucleation	Liver and subcutaneously	10	Microscopic examination of original tumor	Indigestion; abdominal pain for six months	Unknown
10	55M	Eye	Enucleation	Liver; lungs; bones, and subcutaneously	10	Biopsy elsewhere, sarcoma	Subcutaneous and abdominal tumors for two months	Unknown

ter under different legal conditions. The knowledge of delayed metastasis of malignant melanomas may be of prime importance under such circumstances

The treatment of malignant melanomas is unsatisfactory, they show practically no response to any type of irradiation therapy

SUMMARY

Ten cases of malignant melanoma arising in the skin and the eye with removal of the primary growth followed by delayed metastasis over periods of five to thirteen years are recorded.

These tumors recur and metastasize in various ways by local recurrence, by metastasis to the regional or distant lymph nodes, by widespread metastasis throughout the body, especially to the liver, or by a combination of these. It is the dissemination of metastases and not the primary growth which leads to death

A conception is presented of the mechanism of delay in growth of the metastatic areas

Studies of these cases reveal the value of the long-time study of a given disease in an individual case so as to become familiar with the complete life cycle of the disease

The Hospital

Its Relation to the Community and to the Medical Profession*

By WINFORD H. SMITH, M.D., *Baltimore, Md*

IN the aggregate, the operation of the hospitals of the United States falls in the class of Big Business. With less than one thousand hospitals fifty years ago, we now have 7,000 hospitals in the United States. The value** of the hospital plants is about three billion dollars. The annual cost of maintenance is about 900 million dollars. The amount spent for new construction each year is 200 million dollars. The hospitals provide over 900,000 beds, in which every day there are over 700,000 patients. There are over 650,000 persons*** employed in operating hospitals, not including doctors and nurses. These hospitals treat about 12,000,000 patients each year. Further elaboration is unnecessary before this audience. I ask you to keep this picture in mind, however, with reference to topics which I shall discuss later.

Time would not permit a full discussion of all phases of the subject assigned to me. Therefore, I shall con-

fine myself to a discussion of some mooted questions. That there are such questions you well know. One has only to think of the numerous articles, by both medical and lay writers which have appeared in magazines and daily papers during the past few years, to be convinced, not only that there are questions requiring answers, but that there exist both general interest in and general lack of accurate information concerning most points under discussion. These articles deal with the cost of hospital service, doctors' fees, nurses' fees, the amount of free work done both by hospitals and doctors, in fact, they constitute a general discussion of the cost of medical care.

Doctors criticise (a) the cost of hospital service, particularly to private patients, (b) the cost of nursing service; (c) the amount of out-patient service; (d) the creation of diagnostic clinics, (e) the lack of accommodations for people of moderate means, and (f) the closed staff organization.

The question of costs will be discussed later. With reference to Out-Patient Service, there is no doubt that this phase of work has been much extended in recent years. There are now 5,000 dispensaries for poor people. These have been established to meet a

*Read at the Baltimore Meeting of the American College of Physicians, March 24, 1911.

**Estimated The Public's Investment in Hospitals.

***Estimated Personnel-Positions of the Hospitals in the Cost of Medical Care.

real need in the communities served and have, in most instances, been sanctioned, if not recommended, by the staff members or medical boards of the hospitals. Rarely have such enterprises been undertaken by trustees or hospital managers independently of the staff. Can any one doubt the need of such services? Not if one were familiar with the types, and the large number, of patients flocking to the dispensaries.

Much has been said about dispensary abuse by patients. Repeated investigations have shown that such abuse is at a minimum, rarely, if ever, over two per cent. This would seem very low, probably no greater than the abuse of doctors' private offices. On the other hand, the hospital is criticised, if its officers attempt to check carefully the claims of the patient for free treatment or treatment at a low fee and if patients are admitted free. The same criticism applies to the admission of in-patients. In other words, the hospital is damned both ways. I believe it not only right, but desirable, that patients should be made to pay something, if possible. To make it too easy to obtain free treatment would be bad from every point of view, both for the patient and the doctor. Furthermore, comparatively few persons will choose a dispensary service except for the sole reason that they cannot afford to pay for the service elsewhere.

Patients are often admitted to dispensaries who pay a fee equal to that charged in some private offices. This is criticised. This does not occur often enough to offer any real competition and in most instances, this initial fee is seldom repeated, although the pa-

tient returns repeatedly for further treatment. It would be unsound practice to send such a patient away only to return later for continued treatment. There are many faults in our system, but they are not confined alone to the hospital or dispensary.

Recently articles have appeared berating the system which depends upon the gratuitous service of physicians. One writer suggested that physicians might organize and refuse to serve on the staff of any hospital or dispensary unless paid. I am sure that such a suggestion would be condemned promptly by the profession as unwarrantable and foolish, certainly it would be condemned by all who gave serious consideration to our system of hospitalization and its support. Of this I shall speak later. It is undoubtedly asking a great deal of busy doctors to give their service to the operation of dispensaries. On the other hand, many physicians have found it instructive and helpful in building up their experience which, particularly to the young man and the internist, is his greatest asset. The same is true to an even greater degree of the service rendered in the care of patients in the public wards of hospitals. Under the present system, the man who obtains a staff appointment, which calls for some of his time in caring for ward patients, receives quite as much as he gives, except, perhaps, those who have long since become well established and no longer need the hospital service for the experience and the prestige which such a connection undoubtedly gives. It is obvious that until a more stable basis of hospital support is found, hospitals will not be able to pay physicians

for services to the poor in the public wards and dispensaries

The development of diagnostic clinics for people of moderate means is not at present a great menace to medical practitioners, but it may be a factor of considerable importance in the future, unless the medical profession finds some other way of satisfying public demand. Undoubtedly, in the present era of specialization, people of moderate means feel that they simply cannot face the bill, resulting from being referred from one specialist to another, and some other system must be devised. Perhaps more well trained general practitioners will be the answer, perhaps group practice, as advocated by many, will be the answer. But if the latter, it must be on a basis of an inclusive fee, not separate fees of individual men merely grouped together for convenience and for cutting down overhead. In any event, the medical profession should find the solution, not the hospital, not the state, not the public health administrator; although, possibly, all should cooperate. However, some, or all, of these agencies will attempt the solution independently unless doctors attend to the safeguarding of their own field.

That hospitals have, in the past, paid too little attention to the provision of accommodations for people of moderate means is undoubtedly true. Such is likely to happen in the rapid expansion of any system, particularly if as haphazard as that of hospital development in this country. We concentrated first on the care of the poor; next came the provision of accommodations for the well to do. The reasons are ob-

It was necessary to provide for the poor because in no other way could they obtain proper care. The development of more complicated methods of diagnosis and treatment, and particularly the developments of surgery, made it desirable to provide at least the same opportunities of service for those who could pay as for those who could not. Furthermore, it has been the theory that by carrying a goodly number of private patients who could pay well for their accommodations, the overhead would be so distributed as to make it possible to render service to a larger number of poor persons. In more recent years it must be admitted that, in many hospital developments, perhaps undue attention has been given to the private patient class, particularly where those developments have been financed by general public subscription. Here it must be admitted that perhaps doctors have a right to criticize, because it has not infrequently happened that the public probably provided the funds under some misconception. It has been universal practice in campaigns for funds to emphasize the service to be rendered to the community, implying, at least, service to the poor and unfortunate. In reality, such movements have often resulted in the building of hospitals from funds raised by popular subscription which were very largely for private patients and for the benefit of a comparatively small group of doctors. Those doctors on the outside have had ground for criticism. Had the campaign literature or pronouncements stated frankly that so many beds would be provided; that most of them, the exact number being stated, would be for private patients;

that only staff members, would have the privileges, their names being given, no criticism would have been justified. But such campaigns have seldom been run on such straightforward and businesslike lines.

In recent years more attention has been paid to the people of moderate means. Hospitals are now attempting to provide this class with suitable accommodations at rates within their means. That this service has been lagging is not alone the fault of hospital trustees and administrators. We are all at fault. But some questions remain to be answered. Can such accommodations be provided at rates which will make the service self-supporting or must such a service be endowed? No definite answer which can apply generally has yet been found. Such a service can be made self-supporting in some localities, but, in determining where and how, we must consider the type of service to be rendered, the community to be served, the type of building required, the restrictions of the building code, and so on.

In large urban centers, where fire proof construction is demanded and where the most complex type of medical and surgical service is demanded, this question has not yet been answered satisfactorily. Boards of trustees are often faced with the situation that funds at their disposal have been given for charitable purposes and may not be used for this purpose. Therefore, unless self-supporting, endowment funds must be obtained. If a building is required, that means additional funds for that purpose. The Massachusetts General Hospital in Boston has embarked in this field in

a manner which should shed much light on the subject. It is important to know that the authorities of this institution decided, after careful consideration, that a building accommodating 300 patients represented the right sized unit which would offer a chance of operation on a self-supporting basis. An initial gift of \$1,000,000 was supplemented by other funds, bringing the total to about \$2,000,000 for the building. One of the large foundations promised \$150,000 to help offset any deficit for the first three years of operation. The prices range from \$4.50 per day for a bed in a nine bed ward to \$6.50 per day in single rooms. There are extras for operating room, x-ray, laboratory fee, etc. This unit, known as the Baker Memorial, has been open not quite a year and it is too early to know exactly how this experiment will work. It is significant that the authorities have stated publicly that such an undertaking could not succeed without the cooperation of the medical staff, the members of which agreed in advance to limit their fees to the patients in this building.

The closed staff is also criticised by doctors. The limited, or so-called closed, staff is generally favored for several reasons. It is believed by many that a carefully selected staff, members being chosen because of demonstrated ability and a capacity to work in harmony with others, will result in a more workable unit, with the maximum of standardization in all procedures, and will result in better care of patients and more economical operation. I believe this has been demonstrated to be true. There can be no argument on the point that all doctors are not of

equal ability. Not all members of a closed staff are of equal ability, but if the principle is sound and its application is made solely on the ground of ability, then that staff should be composed of men competent for the work assigned to them, supplementing each other and forming the best type of a working organization.

The Trustees must be satisfied that members of the Staff are competent and responsible, because in many states charitable hospitals are not liable for damages provided the governing boards have exercised due care in the selection of their officers and employees. It is also a fact that if poor work is done or glaring mistakes are made by a doctor in treating a patient in a hospital, the reputation of the institution suffers quite as much as that of the doctor concerned.

The point has been made that all public or community hospitals should be open to any reputable physician or surgeon in that community, arguing that only in this way will the general level of practice be kept on a high plane. That is yet to be demonstrated. On the other hand, I believe that if such a system were followed, those hospitals would not be as efficient in operation, nor as productive in developing outstanding men, nor in clinical and laboratory investigation, as under the restricted staff type of organization. Human nature is such that no matter what organization is adopted, even if all doctors were accorded hospital privileges, a considerable number, because of personal characteristics, environment, background, or general incapacity, would always remain in the way of the best. In any event, the

welfare of the patient is the first consideration.

We must admit that the public at large has a definite interest, often a vested interest, in the welfare of hospitals. Yet the public is not well informed and, in consequence, is unduly critical. It is perhaps our fault that the public is not better informed. Some of the misinformation or lack of information is due to the manner in which appeals for funds are made, a point which I have already touched upon. Then, the public's advisors, as represented by the medical profession, are not always well informed because they are too busy to give careful thought to the subject and sometimes these same advisors are too ready to agree with the public. It is always open season for hospitals. It seems to me a very short sighted policy on the part of physicians, to criticise, as so often happens, without any constructive effort, those institutions which mean so much to the profession by way of the opportunities provided for their convenience and which are absolutely essential for much of their work. These men with hospital privileges have provided for them, and without cost to them, more facilities than are provided for any other professional group.

The public is critical of the cost of operation, resulting in numerous appeals for funds and high charges to patients, and because patients are sometimes turned away. The last point is often played up by newspapers. It should be obvious that a hospital, like any other building, has limited capacity, and even an urgent case must at times be referred elsewhere.

Furthermore, why should a hospital be expected to do more than its finances permit? In this period of unemployment, hospitals have been hit hard because of the increased number of patients unable to pay. For the most part, they have assumed the extra burden without assurance of additional funds. It is expected that hospitals will do this humane work. Are hotels expected to feed the hungry, do railroads and street cars transport the poor and unemployed free of charge, and do stores supply the necessities of life to these people without cost? Certainly not, no one expects it. But hospitals are expected to assume the burden on the theory that the public supports them. All would be fine if this were true.

Hospitals are expensive institutions to operate, much more so than twenty years ago. Why? For the same reason that the cost of living is much higher. The character of hospital service is much more thorough, more efficient, and more complex than formerly. The quarters provided have been made increasingly more elaborate, more comfortable, and are provided with equipment for efficient service far beyond the provisions of earlier years. Any medical man familiar with hospitals will concede these points without debate.

To be more specific, all articles of food and supplies of all kinds, cost much more. The old system of hard, soft, and liquid diets is no longer sufficient. We must have well organized dietetic departments which will provide diets of many kinds and varieties; cardiac, nephritic, diabetic, high calorie, low calorie, salt free, high protein,

low protein, and so on. This involves not only a constantly greater variety of articles to be prepared, some unduly expensive, but also infinitely more labor in preparation and service.

The service is much more complex, as exemplified in the greater care with which patients are studied, the more numerous tests employed, such as x-ray, fluoroscopic, basal metabolism, blood chemistry, bacteriological, serological, physiological, and biological. Treatment is also more complicated. More nursing service is required, larger resident staffs are needed, and likewise, more employees of all types. The modern hospital now requires a working personnel of about two persons for every patient and sometimes more. The planning of a hospital now provides smaller units for patients, the large open ward belongs to the past. This is necessary for the proper segregation of patients and their greater comfort. Hospitals cannot, and should not, rely entirely upon student nurses for nursing service as was the case in the past, with daily duty covering 12 or 14 hours. Shortening the working day for nurses, providing maids to do many of the household duties formerly assigned to the pupil, and the employment of more graduates, has increased the cost of operation enormously. The extensive developments of out-patient service, of social service, of follow up, of efficient record departments, provision for hydrotherapy, electrotherapy, light therapy, radium therapy, mechanotherapy, are all factors which have entered into the increased cost of hospital operation. They have all resulted from the demands of the profession because of increased knowl-

edge of disease and its treatment. No one should find fault with that

In discussing the attitude of the public towards the numerous appeals for funds we must all have some sympathy. We must go back to the basis upon which our hospital movement was conceived in order to explain the situation. In these days of super-efficiency, every enterprise not yielding a profit is under question. The vast majority of our hospitals are small, providing less than 125 beds each. They are financially handicapped to begin with, and must do considerable free work. Where can such hospitals obtain competent, well trained business managers? They are not available for such small institutions. These hospitals, therefore, for the most part, must rely upon nurses as managers. Have they been taught business management? No more than the doctors. A more conscientious group of workers it would be hard to find, most of them are overworked, are trying to do effective work for which they have never been trained, and are worried and harassed all the time. Sometime there will be a place where they can be trained specifically for such a job and then, perhaps, the job will be better done and they will command larger salaries and worry less. But I am sure that no more sincere and conscientious effort will go into their work. Until that time comes, however, these hospitals and their communities will have to be content and would do well to appreciate what they have.

Governing boards should know what the job demand, should know what qualification the persons possess

whom they select. If they are unable to obtain those who are thoroughly competent, they should help those whom they do select, not condemn them. Of course, changes are often needed, but those institutions which change managers every year or two frequently have something wrong with them other than the superintendent.

The larger hospitals, able to pay for competent service, are, I believe, for the most part, well managed. You cannot compare a hospital with an industrial plant with its well paid skilled labor and closely knit organization, all operating to the end that a standardized product shall be turned out as economically as possible, all costs being absorbed and a percentage added for profit. Hospitals are not engaged in that type of business. The hospital industry is engaged in mending broken bodies, in removing diseased tissue, in taking a machine which is out of order and causing it to function smoothly once more, and to continue functioning. No two problems are quite the same because no two individuals are quite the same, either physically or mentally. Furthermore, while we can and do carry business methods into every phase of hospital operation, there is a point where standardized procedure and business methods stop. That is where the doctor begins to function, in the professional care of patients. The doctor is successful because of his own individuality, his own method of doing the job, and his own personality. He is individualistic in his methods and it would be a sad day when the attempt was made to standardize him, if it were successful.

I referred to the basis upon which our hospital movement is founded. Has the growth of the hospital movement resulted from a carefully studied plan based upon the needs of the population? Have the 7,000 hospitals been established according to a definite program of so many beds per 1,000 population, so many beds for this branch of medicine, so many for that, based upon the needs of the communities to be served? You know that such is not the case. Is the movement the result of well established policies of the state for serving its citizens, such as the principle underlying our public school system? It has been a haphazard development depending for the most part upon the medical profession and groups of interested laymen and is based largely upon the principle that it is the duty and privilege of people of means to provide for their less fortunate neighbors. It is a beautiful principle and it has worked remarkably well, but is it sufficient to meet the requirements of the future?

The time has come when haphazard methods should be replaced by logical, sound methods based upon facts and sound principles.

To be more explicit, we have our Boards of Education which determine the number and type of schools needed, we have Chambers of Commerce, and Commissions for Industrial Development to look after the commercial interests of cities. Is it not equally important that we have some machinery to consider the hospital requirements? To be sure, we have our State and City Charity Departments and Health Departments, but considering the handicaps under which such departments operate, we would none of us wish to

place our hospitals under those agencies. I make the point that the time has come when there should be machinery of the State or the municipality which should concern itself with such questions as "Is another hospital needed, where, of what type, and how is it to be supported?" I do not mean that it shall run the hospitals. But such a commission should determine the needs of the community and should pass upon all new projects before they are undertaken and so long as our hospitals must depend largely upon public support, should determine how much of the expense should be borne by the State or its political subdivisions and how much by private philanthropy.

Of all the hospitals in the United States:*

- 49 per cent are of the private or corporate type,
- 26 per cent are federal, state, or municipal in type,
- 25 per cent are private or commercial in type.

We know that, generally speaking, the states and counties concern themselves principally with hospitals for the tuberculous and the insane. The cities provide some general hospital beds but not nearly enough. There are 5,600 community hospitals of which 4,300 are general hospitals. Generally speaking, excepting for the insane, the tuberculous and veterans in Federal Hospitals, the care of the sick poor rests largely with the corporate or community hospitals. Is this statement well founded? A recent survey** of the hospitals in Philadelphia

*Publications of the Committee on The Cost of Medical Care

**By Nathan Sinai, D.P.H., and Alden A. Mills, Committee on Cost of Medical Care.

disclosed that 40 per cent of all patients in all hospitals were free. In New York City, the 30 general hospitals participating in the proceeds of the United Hospital Fund provided, during the year 1929, 2,532,000 days of treatment, 44.2 per cent of which were free. These are certainly fairly typical of the situation in the east and perhaps to a lesser degree, in the west; where more general hospital beds are owned, and operated by the state and its subdivisions.

Who pays for this free work? The Survey in Philadelphia disclosed these figures for the 52 hospitals. Of the gross income available for operating these hospitals (excluding the Philadelphia General—a city institution)

- 58.7 per cent came from patients
- 16.5 per cent come from endowments
- 4.8 per cent came from cash contributions
- 9.5 per cent come from Federations
- 7.4 per cent come from public support—city

In other words, these hospitals did 40 per cent free work and received from public funds 7.4 per cent of their total revenue and had a total deficit aggregating \$355,779.00

I fancy this is quite typical of most cities varying, perhaps, slightly up or down. And yet, in most states, if not all, real estate owned by these private hospitals for purposes of revenue and even the endowment funds, the income of which is used for the poor, are taxed by both state and city and at the same rates as any other real estate or realty which may be owned and not for the profits of business or of a charity.

It is worth while to analyze the above figures somewhat further. About 43 per cent of the money available for operating these hospitals comes from sources other than payments of patients, and of this 43 per cent, only 7.4 per cent comes from public funds so that about 35 per cent comes from endowments, cash contributions, or the federations, which means, that in one way or another, this amount comes from private philanthropy.

It is significant that at this time, with the long history of the development of American hospitals back of us, the total endowment fund of hospitals is estimated to be \$437,000,000;* of which \$15,000,000 is for governmental, \$3,000,000 for proprietary, and \$419,000,000 for the community or non-profit hospitals. This amount of endowment for the non-profit hospitals is sufficient to fully endow 13,967 beds, of which there are 247,970 in this group of hospitals. The endowment is only sufficient, therefore, for 5.6 per cent of the beds. It is further significant, that of the 2,604 hospitals operating on the non-profit basis, only 1,060 control any endowments, and of this number, 125 hospitals control 45 per cent of the total, and only 31 of these control more than \$2,000,000 each. Many hospitals in the United States do not receive endowment income in sufficient quantities to materially affect their financial policies. The point of all this is that the system is not sound, that with the increased cost of hospital operation, it is doubtful if the present

*Figures supplied by Rorem in his book entitled 'The Public's Investment in Hospitals.'

system of support will prove adequate for the future

We certainly must not discourage private philanthropy, but would the system not be on a better basis if the burden were more equitably distributed by requiring the cities and states and counties to pay more nearly what it costs these hospitals for caring for the poor? It is stated that dependent persons are ill, on the average, nearly twice as often as persons with incomes considered adequate. The U S Children's Bureau,* in a study of 22,967 births, between the years 1911 and 1916, in eight cities, found that in families, where the earnings of the father were above \$1,250, there were 59 deaths per 1,000, that the number of deaths of infants increased per 1,000 the lower the earnings of the father for example, earnings \$850 to \$1,050, deaths 82.2, earnings \$650 to \$850, 107.5 deaths. Warner in American Charities gives illness as a cause of dependency in from 20.1 per cent to 43.7 per cent of dependent families. Considering these facts, would it not seem to be quite as important that we provide adequately from public funds for the care of the sick and for public health generally, as for education, for good roads, bridges, and harbors, all at public expense? Certain it is that until this or some other method is found, the public must expect appeals either separately or through community chests.

The public also protests against high charges in hospitals. In the 30 general hospitals in New York City, referred to above, the average daily

per capita cost was \$6.79. Generally speaking, we may say that the average per capita for general hospitals is probably at least \$6.00 per day. If the cost of public wards was distinctly separated, still the cost would be considerably more than the average charge in the public ward, which is generally about \$3 per day, rarely more than \$3.50. That does not seem high. To be sure there are extras, but for ward patients these are usually reduced to a minimum or remitted.

Private room rates are much higher, ranging in the more expensive types of service, from \$7.50 to \$15.00 per day, depending on size, location, with or without bath, etc. The average per capita cost for private room service is without doubt higher than the lower priced rooms, probably about the same as the average price charged for rooms. As a business proposition, this is not excessive, when one considers that the public will cheerfully pay the same price at a hotel and get much less for the money. In the hospital one receives, in addition to his room, three meals a day, some nursing care, services of the resident staff, orderlies, and maids, ordinary medication, surgical dressings, etc. To be sure, the extras are heavy in most hospitals. I think the principle of charging extras on a cost basis would be sound if credits were likewise offered where standard service is not used, but this would entail a complicated system of accounts and even hotels do not do that. Generally speaking, I believe it would be better to eliminate all extras, if practicable. Many hospitals have gone part of the way in this, but I do not think we can go all the way, in

*Frank J. Brewer, Hospital Social Work, Washington, D. C.

fairness to the average patient, who would thus be obliged to pay for the fads and fancies of the rich or cranky individual whose demands either directly, or indirectly through his physician, are often excessive. In determining the question of costs per day for private patients, it must be remembered that in most instances the buildings are given to the hospital and it is rare that hospitals include in operating costs any interest charge on capital invested or any allowance to be set aside to care for depreciation and obsolescence.

There is considerable criticism of the charges made by graduate nurses and of the need of employing graduate nurses in hospitals. I believe the charges of graduate nurses are not too high. They work long hours and must deal with situations which are most exacting, and sometimes, most unpleasant. They have periods of unemployment, sometimes long periods. The private duty nurse earns, on the average, between \$1,200 and \$1,300 per year, and her years of active service are limited. She is indispensable and her lot is hard, although satisfying from the standpoint of service. By comparison with other lines of employment open to educated women, her earnings are too small rather than excessive.

As to the complaint against the need of employing special nurses in hospitals, a survey was made by a national committee covering 1,822 private patients who had specials and this showed that in 40 per cent of the cases the doctor urged a special on account of special care needed, in 33 per cent the family wanted a special,

in 22 per cent the patient felt the regular service inadequate, in 3 per cent the hospital suggested one, and in 2 per cent the reason was that their friends always had one. I believe, however, that hospitals should provide more adequate nursing service, but they cannot do it under the present system.

The average duration of stay in the hospital, particularly for most surgical patients, is about half as long as was the case 25 years ago. This means that even if the hospital charge is double, the total hospital bill for that type of patient would be no greater than it was 25 years ago.

Considering all of these factors, I believe the charges are not out of line, although they seem high when the hospital bill, doctor's bill and special nursing fees are totaled. I believe the complaints rarely come from the man who can afford it, but generally from those less fortunate in this world's goods, which probably brings us again to the needs of those of moderate means.

Then, too, we must take into consideration that the average man has made no provision for illness. He resents illness anyway, and doubly resents the attendant expense. He has not denied himself in other respects, however. Wingate Johnson, in an article in the March "Atlantic Monthly" furnished these figures on the expenditures of the average family. He compares the cost of medical care with other items of the average family expenses per year:

For doctors	\$21
For medicine, chiefly patent	25
For hospitals	15

For nurses	8
For pleasure automobiles	150
For tobacco	67
For candy	37
For gasoline	37
For theaters	35
For soft drinks, ice cream, etc	34

In the study of the cost of medical care in Philadelphia, conducted by Nathan Sinai and Alden B Mills of the staff of The Committee on The Cost of Medical Care, the total bill for medical care is given as follows

Total cost			\$104,000,000
For physicians, dentists, nurses, and cults			47,000,000
Physicians	\$27,000,000	Principal items of the above figure	
For dentists	13,000,000		
For osteopaths, chirop, midwives, etc	3,000,000		
For patent medicines	obtained in drug stores		9,000,000
For prescriptions			7,340,000
For home remedies			3,692,000
For miscellaneous medical care sales			2,380,000
For hospitals, sanatoria, etc			16,000,000
For indirect costs not included in operating costs of hospitals			7,206,000
Some other minor items are not given here.			

The point is that the total cost of operating all of the hospitals is not the largest item by any means. The public spent for medical care sales in drug stores, a total of \$22,986,000, of which over \$13,000,000 was for patent medicines and home remedies.

But it is of little use to criticise the public because it spends so much for home remedies and patent medicine. While it is true that if there was less high pressure salesmanship and people spent less for radios, automobiles, electric refrigerators, electric washing machines, movies, etc., they would have more money with which to meet doctors' bills and hospital bills, finding fault will not remedy the evils of the situation. We shall doubtless face these same problems for a long time to come, but it is well to know the facts.

Many remedies have been suggested,

and among the most prominent have been

The formation of guilds for the purchase of medical and hospital service,

Health insurance, compulsory or voluntary,

State medicine

I am sure you have definite ideas on these subjects. The guild idea may be a good one; it sounds attractive, but in our present state of social development, and particularly in the larger

cities, I doubt if it would appeal to the class which presents the great hospital problem, the free and part pay patients. The same applies to insurance, unless compulsory, and therein lie dangers of many varieties.

In the very multiplicity of agencies and individuals concerned in the provision of medical care lies perhaps an outstanding weakness in our present system. It may well be that from the medical standpoint, the greatest need is not for more hospital beds, not for more doctors, or more public health activities, but is an agency for the organization and co-ordination of all medical facilities so that each may render its greatest usefulness to the public and may co-operate most effectively with all others in best serving the interests of those concerned in purchasing and paying for medical care.

The Profession and the Public*

By GEORGE EDWARD FOLLANSBEE,** M.D., *Cleveland, Ohio*

THERE are two points of view from which to look at medical economics, that of the profession and that of the public. The standpoint of the members of the medical profession has been consistently occupying the pages of state and other medical journals for years. The complaints and arguments of the doctors have been reiterated until you are familiar with them. The public has had its hearing in many popular magazines and weeklies and in the newspapers. The public never sees the medical journals presenting the complaints of the profession and few of the profession read any large proportion of the complaints of the public in the magazines. Neither side has a proper appreciation of the other.

I wish to bring to your attention some thoughts aroused by some of the more moderate criticisms by the public against our profession. In doing so I wish to be understood plainly as making no malicious charge against an honorable profession to which I am proud to belong. The spirit is rather

one of analysis and constructive criticism based upon the opinions formed about us by those who are not of us—an attempt to see ourselves as others see us, a wise thing to do at times.

The great cry is that it costs too much to be sick or to raise a family. I am not interested tonight in any cost except that of the doctor which approximates only about 25 per cent of the entire cost of health, sickness and reproduction. The impression has gained a strong hold on the better educated and more prosperous of the people that a general practitioner is not qualified to practice medicine; he might do as a distributor to direct to the proper specialist, or as a nurse, but that he is incompetent to actually take the responsibility of the care of illness, accident, childbirth or that latest entity, a healthy baby. So specialists are called and visited, clinics where routine methods multiply costs are sought in many trivial complaints, the costs rise and the medical profession is berated for excessive charges and accused of rank commercialism. It is unfortunately true that the profession is contaminated by some members who apparently took their oath to Mammion rather than to Hippocrates, but their number is small in comparison with that great body of men who always have and always will follow the

*Read at the Baltimore Meeting of the American College of Physicians, March 24, 1911.

**Formerly Journal Editor, American Medical Association; Member, Executive Committee, The Committee on the Costs of Medical Care.

ideals of the Hippocratic oath. We apologize to the public because of them. We do not defend them.

The number of self-styled specialists is ridiculous. It should be unlawful for a doctor to present himself as a specialist unless he has had adequate training and taken a degree in his specialty. That is something the medical profession of itself cannot accomplish but it can assist toward that end. Medical schools can revise their curricula as one step, teaching less of the intricacies of the specialties and more of the general course of preventive and curative practice which comprises seventy-five per cent of the family's needs, all of which can be cared for by a properly educated general practitioner. Much could be done toward this end by the thousands of open hospitals refusing their facilities to men for the care of cases which they are unqualified to treat. This is being successfully done today in some open hospitals with striking and convincing improvement in the mortality and morbidity rate, and lower costs to the people for hospital and funeral expenses. Also, the occasional specialist who gets much of his work from similarly unmoral colleagues is likely to overcharge for his services and be unprofessionally insistent upon collection. The temptation to pay commissions is likely to be beyond his power of resistance.

The statement that there are too many specialists applies to cities, especially the large ones, where most of the complaint of the high cost of medical care is made. It does not apply to towns and rural districts. Failing the correction of the rapid diminu-

tion in the number of general practitioners, of the excessive trend toward specialism, of the lawfulness of any or every doctor announcing himself to the people as a specialist, of the present almost prohibitive cost of some essential diagnostic procedures, of the commercializing of our profession by a small minority of its members, the excuse is valid for government and philanthropy and business to take over sections of practice, large or small, which should remain in the domain of private practice. The whole profession and particularly the real specialists should support the general practitioner and encourage the public to make all proper use of him. A specialist should return to the care of the referring physician all cases sent to him as soon as the need for special ability or special treatment is past. He should refuse to treat those cases coming to him over the head of a family physician when that physician could and would care for the case satisfactorily. It should be beneath the dignity of a specialist to care for such cases.

The older general practitioner is suffering from an inferiority complex. He is depressed and saying little, though he might say much, for he has seen the exceedingly rapid scientific advance of the practice of medicine with which he has been unable to keep pace. He realizes his limitations, but he does not realize that his years of experience have taught him an art of practice which will offset in many cases his lack of scientific knowledge, and of which his young competitor is ignorant.

The graduate of the last few years is quite competent to care for much

of the work that now goes directly to specialists and people should be taught so. We must re-establish the confidence in the general practitioner, the family physician; we must confine the work of the specialties to that requiring peculiar knowledge, ability or apparatus; we must practice medicine for the benefit of the people with financial gain honestly secondary in our thoughts, or inevitably the people with the assistance of private or public philanthropy will provide what we refuse to supply, medical care at a cost they are able to pay.

A very large proportion of whatever cost is excessive is due, not to the profession, but to the people themselves. This appears in the many instances in which people seek the services of the well known and most prominent specialists whose only way of restricting their work to their physical capacity is to charge fees commensurate with their reputation. It is evident in the demands by the people themselves for services of which they have heard but which in the particular case are not necessary for diagnosis or treatment. It is shown in the tendency of the public to look upon physiological pregnancy, child-birth and the rearing of children as a pathological process requiring the service of the specialist in all cases instead of only those with pathological complications. It is manifest in the habit of ignoring the general practitioner and primarily consulting some specialist when in the opinion of the patient is the proper one to treat the condition, only to find that the trouble is a local irritation of a condition not requiring the proper sphere of activity

To the extent that people themselves seek the services of a specialist for conditions which can be satisfactorily cared for by the general practitioner, they themselves are responsible for the excessive cost. Twenty to twenty-five per cent of them do not choose the right specialist in the beginning and so costs are pyramided.

These are matters for which we are only remotely responsible but which we should try to correct by education of the public, by advice and remonstrance to our patients, by recognition of the utility and ability of the general practitioner and by upholding the dignity and standing of the specialties by confining their work to conditions requiring expert ability and knowledge. We have a more direct responsibility in respect to those practices which are under the direct control of the members of the profession themselves.

Fault is found justly or unjustly with the practice of medicine in too many ways to consider all of them. The principle complaints are, (a) excessive charges for operations, (b) prohibitive expense of children, (c) unwarranted cost of diagnosis.

OPERATIVE COSTS

Excessive charges for operations refer of course only to the surgical specialties and complaint is made most directly and most frequently against general surgery.

There was a time not many years ago, when a specialist was a specialist by virtue of his superior ability and because the general practitioner expected to care for all the illnesses and accidents occurring in his clientele ex-

cept those of major severity. These he referred to a specialist if one was available. Graduates of those days were impressed with the dignity and exclusiveness of expert special work and had deep respect for the responsibility involved in major procedures.

As medical education and technique advanced, ideals as well as the training of the student changed. Specialties were divided on a basis of anatomic fields instead of personal ability. The idea grew that any condition occurring in an anatomic field belonged to that anatomic specialty. The change to this conception magnified the available field of the specialty to the student, minimized his comprehension of the knowledge and ability required and blunted his conscientious appreciation of his responsibility, until now the intention and expectation of the majority of graduating interns is to enter at once on the practice of a specialty in its entirety, usually general surgery, following general practice only so far as needed as a stepping stone to full specialization.

Many surgical procedures which formerly were considered major, by virtue of advancement in knowledge, technique and hospital routine are now essentially minor. The present graduate who has served his time as intern and resident is competent to perform many operations which formerly justly belonged to the surgical specialist. Should these men restrict their ambition to operate to those cases in which they are competent; should the surgical specialist admit the competency of these men in this limited field, should the public be educated to accept them for such opera-

tions, should these men themselves recognize that the operations which they are competent to perform are essentially minor and regulate their fees accordingly, much of the cry about the excessive charges for operations would be stilled. By recognition of this principle many would be satisfied to be general practitioners who now aspire to be specialists, and the hospital mortality and morbidity rate would be reduced. A recent survey of the physicians of two of our large cities shows that on the statements of the individual physicians themselves, twenty-eight per cent are complete specialists, thirty-seven per cent are partial specialists and only thirty-five per cent are general practitioners. The people cannot support a medical army with so many generals. There must be more privates. The effect of present medical education and professional aspiration has been to increase the field of the specialty and along with it the number of specialists, and as a necessary corollary has restricted the field for, and the number of, general practitioners. The opposite should occur.

The tendency of partial specialists to over-value their services has already been noticed. The code of ethics for years has declared that too low charges are unprofessional, on the basis of harm to the public. Too high charges are harmful though for a different reason and are equally unprofessional. This matter therefore is to a degree under the control of medical organization. In so far as this abuse exists and comes to the attention of medical organization, in self-preservation and devotion to professional ideals cogni-

zance should be taken, for the reputation of the whole profession is sullied by the reprehensible acts of comparatively few.

CHILDREN COSTS

The popular cry that the production of a family of children is too expensive now-a-days invites one to ponder the cause of such a condition. Some years ago the birth and raising of children was taken as a matter of course quite like the buying or building of a home. The greatest concern until the child entered school was the furnishing of food and clothing. It was all normal like other health. The confinement which turned out badly was looked upon as a "sickness" just as was any other departure from health. Today, how different! The human being from germinal cell to school age, in the popular attitude, is a pathological entity and the process of its being seems to be accepted as pathological throughout its course, except at its beginning. During the last ten years the act essential to impregnation has been transferred from the moral and spiritual field of contemplation and is now generally allocated to the purely physiological. On the contrary pregnancy, child-birth, infancy and childhood have been transferred from the physiological to the pathological field. Quite naturally, the result has been to increase cost. Green-houses tomatoes cost more to produce than field-grown ones.

The patient is not to decide all present and future obstetric specialists, pediatricians and pediatricians. They are to be the best of their kind but they are to be the best of their kind.

grown up a mild national hysteria on reproduction which is involving the major portion of the populace wherever the various specialists can be found. Who started it and who keeps it alive, whether political public health or voluntary charitable agencies, the medical profession or the people themselves, will be answered according to the point of view of the individual answering. But whoever is responsible, the system has been over promoted. It is costing too much and we should return—not to the former status but to a common sense basis. What is there so profound or abstruse about prenatal work or raising normal babies that a general practitioner is incapable of giving satisfactory service? What expertness is needed in a normal confinement that requires a high priced specialist to be within call while an intern and obstetric nurse watch the progress of labor so as to call the obstetrician at the proper time to be present at the delivery?

The general practitioner is sufficiently well trained to do all a specialist does in a normal confinement, or should be if he is not. The field of the obstetrician and the pediatrician should be in the abnormal or unusual case, called in by the general practitioner when his skill is insufficient. Babies and children do cost too much under the present system but the system should be changed. Our part in the change individually and collectively, is to educate the people to "render unto Caesar the things that are Caesar's" and to teach the general practitioner to "render unto God those that are God's." Pressure should also be brought on medical colleges, if needed.

to educate the student sufficiently well in obstetrics and pediatrics to give all needed care to normal cases and be able to recognize those conditions which need knowledge and ability beyond his own. The public will be benefited. The general practitioner will be elevated to his proper dignity in the profession. The specialist will lose none of the work which properly should be his.

I have chosen to speak particularly of those specialties about which complaint is made most loudly by the layman. Critical examination of others would develop some justifiable cause and lead to corrective suggestion. Internal medicine while not yet subdivided to the same extent as surgery, is tending that way, much, I believe, to the detriment of both public and profession. And it has its weak spots.

DIAGNOSIS COSTS

I will conclude this critical, and I hope, constructive analysis by discussing the third feature calling down upon our heads the greatest amount of complaint, the unwarranted cost of diagnosis, a subject which involves us all. Diagnosis! The interesting case! It is the most attractive game in medical practice. It is to medicine as the mystery story is to literature. We all play it. We all are entranced with it. The autopsy or the operation proving our acumen is like the reading of the last pages of the story to test our accuracy of deduction. Without that last proof we are unsatisfied.

Tests in chemistry, bio-chemistry, physics and physiology have multiplied until we are bewildered by the signs, reactions, interpretations and

indications. And many of these cost money. Someone must pay. If the patient can he must, though the cost of scientific laboratory diagnosis may overshadow the other expenses connected with his illness. If all these are needed to make a diagnosis or direct his treatment he should pay for them. But many such expensive procedures are carried out which are not essential to correct diagnosis. They are the luxuries of medical practice. The rich want them and should have them. The man of restricted means may want them but he should not have them. They are sometimes ordered for the doctor's own satisfaction or to teach interns. Such a use is proper in the case of the rich or the free patient but is unwarrantable in the case of the ordinary pay patient. When a doctor orders examinations for which the patient must pay he is at the time the guardian of the patient, the trustee of his funds. Such meticulous care and sound judgment should be exercised as would be expected of a similar legal relationship. It is the doctor's duty even to remonstrate when the patient in his ignorance suggests or requests needless expensive examinations. There is no relationship requiring such a high grade of honor to exist as that between the patient who places his life and his pocketbook without redress in the keeping of a doctor and the doctor who accepts that trust. It is to the everlasting honor of the medical profession that that trust is so infrequently abused. It is more frequently abused in thoughtless enthusiasm than in willful violation, but the results are the same to the patient.

There is some justified complaint of routinely passing the patient around from one specialist to another because certain anatomic fields may be involved. Needless to say the same conscientious consideration should be exercised as in the ordering of laboratory examinations

The matters which have been brought to your attention are not amenable to change by organized medicine. The change in attitude by profession and public must come from the thoughtful sympathetic consideration, the conviction and the dictum of the scientific leaders of the profession, the members of the special societies. Through these influential men the public can be educated. Public opinion is the driving force which determines policies in this country. The medical profession is no less subject to it than is business or politics. With the help of the sensational, the propagandist and the welfare press a tide of public opinion inimical to the profession is rising which has already become a distinct menace. That the logical result of such opinion as is now being formed, will in the end be incalculably harmful to the people as

a whole will make no difference for the mass of the people do not think logically. The medical men themselves must do the thinking and the educating of the public. The first step in this education is to correct within the profession all justifiable complaints against the practice of medicine that are possible of correction. And all are possible of correction if the scientific leaders realizing the danger have the will to correct. Then we can come to the people with clean hands. Then with sincerity and conviction we can educate the public. Organized medicine has the machinery and the power of defense against adverse opinion but it cannot form public opinion and cannot ultimately prevail against a rising tide. Resolutions and articles in medical journals do not reach the layman and would be discredited if they did. It is only by public and private pronouncement by the scientific leaders, upheld by the influential men of the profession that the change can come. It is to you men of the special scientific societies that the profession must look for leadership.

CINCHOPHEN POISONING A PARTIAL EXPLANATION FOR THE INCREASING INCIDENCE OF ACUTE YELLOW ATROPHY

Acute yellow atrophy of the liver is by no means the rare condition now that it was when it occurred almost solely as a disease of pregnancy and of the puerperium. Since then it has been shown that the toxic necrosis produced by chloroform, particularly in the condition known as delayed chloroform poisoning, is indistinguishable in its pathological features from acute yellow atrophy. That syphilis alone may produce marked changes in the liver parenchyma came to be generally accepted and in combination with arsenical therapy, syphilis was found to give the full clinical picture of acute yellow atrophy. In susceptible individuals arsenical drugs alone and in usual therapeutic doses were proved to be sufficient. In the munitions factories during the war and in industrial uses since, such substances as trinitrotoluene, trichlorethane and carbon tetrachloride have been found capable of producing extensive hepatocellular necrosis of this same general type. The parenchymatous lesion of phosphorus poisoning is distinctive in its early stage by reason of the diffuse fatty degenerative infiltration which it produces, but in the reparative stage it may be confused with the hepatitis produced by the other agents mentioned. Some have claimed that alco-

hol found in combination with other substances in home-distilled and synthetic beverages, is the cause of the increase in acute parenchymatous degenerative hepatitis of this type. Moreover, most of these livers now are not seen in the acute stage by the pathologist, but only when reparative changes are well established, with extensive bile duct proliferation as an attempt at liver regeneration. These are examples of what may well be termed subacute 'acute yellow atrophy' and chronic 'acute yellow atrophy'—a true toxic cirrhosis in a reparative phase. There is full proof that the cinchophen (phenylquinolinecarboxylic acid) group of drugs has had a share, how important can only be surmised, in increasing the incidence of acute yellow atrophy of the liver. Although 'atophan' was introduced in 1908, it was not until 1925 that the first report of a fatality from the use of this group of drugs appeared, but the occurrence of jaundice had been previously noted in numerous instances. Since 1926 the cases have multiplied rapidly. Within the last few months several excellent papers* have appeared giving evidence

*PARSONS, L., and HARDING, W. G., Cinchophen (atophan) poisoning, report of four cases, *Am Jr Med Sc*, 1931, clxxi, 115-125, SHERWOOD, K. K., and SHERWOOD, H. H., Acute toxic hepatitis (acute yellow atrophy) due to cinchophen, *Arch Int Med*, 1931, xliii, 82-88, BEAVER, D. C., and ROBERTSON, H. E., The specific character of toxic cirrhosis as observed in cinchophen poisoning, *Am Jr Path*, 1931, vii, 237-257.

of the widespread interest in this condition. Beaver and Robertson have reported five fatal cases from the Mayo Clinic and have described in detail the various stages of the liver injury and its attempted repair. Sherwood and Sherwood collected forty-eight cases from the literature and added one. From these cases they have built up a composite clinical picture which is exactly like that of acute yellow atrophy as formerly known. In some instances symptoms have arisen as late as ten days after the cessation of administration of the drug. At first there is nausea and gastric irritability followed shortly by the onset of jaundice, biluria and pruritis. The jaundice deepens and at this stage progressive decrease in the size of the liver can be demonstrated. By the third and fourth week, if the patient is not to recover, the jaundice and toxemia have increased and splenomegalia, ascites and edema of the extremities may develop. Finally the patient becomes delirious, and then comatose and dies. It appears that re-administration of the drug, even in small quantities, will usually produce a prompt return of jaundice. This indicates, then, that use of the cinchophen group is contraindicated in patients who give either by history or by clinical findings evidence of previous or present liver disease. Unfortunately, physicians are not always aware that various antirheumatic preparations, distributed under sundry trade names, belong to this group. Oxybiphenol, for instance, doxibiphenol and biphenol are all cinchophen drugs and they all of them have produced the same toxic effects. A

predisposition or idiosyncrasy, dependent upon as yet unknown factors, seems to be significant in determining that an acute yellow atrophy will result.

SUICIDES IN THE UNITED STATES IN 1930

According to the compilation by Frederick L. Hoffman which appeared in *The Spectator* of May 14, 1931, there were 6,440 deaths by suicide in 99 American cities in 1930. This yields a death rate from this cause of 20.0 per 100,000, the highest figure since 1915. On the basis of these statistics it is believed that the annual loss of life by suicide in the Continental United States must reach 18,000 to 20,000. The nation-wide industrial and business depression has undoubtedly played a large part in the increase in the total number of suicides for the past year. From the medical standpoint the changing trend in the means chosen for self-inflicted death is of considerable interest. There are fashions and modes in suicide as in all other human activities. We have passed through a period in which much newspaper publicity was given to poisoning by bichloride of mercury and to various means for combatting that condition. As a result, there was an increase in the homicides in which mercurial compounds were the active agent. The suicide record for 1930 shows that jumping from high buildings and other high places is becoming an increasingly frequent method of self-destruction. In many cases it has been found impossible to determine whether death by this means was an accident or a suicide. There were 21

least two suicides recorded during the year of persons who jumped from airplanes while in flight. Extreme caution should be used in guarding high places in various ways, such as by protective devices, and in making it impossible to open the cockpit doors of airplanes except at the will of the operator or an attendant. The annually appearing statistical study of the suicide problem which Hoffman has prepared for so many years has done much to keep this question before the public eye. He properly insists that there is much that is remaining undone which would go far toward preventing this wastage of human life.

MORTALITY RATE FOR THE FIRST SIX MONTHS OF 1931

From various sources come reports that the first six months of the present year have been unusually healthy. Out of the tripartite combination of general business depression, closing hospitals and idle doctors, and general good health, has arisen the opportunity for the columnist and jokester to aim his thrusts at the medical man for it appears that it brings good health when people generally cannot afford medical attention. Others find the explanation in less extravagant living, plainer food and more hours of sleep. However, figures recently released by Dr. Henry F. Vaughan, Commissioner of Health, giving the mortality record for the City of Detroit for the first

six months of 1931 show very clearly that the reduction in mortality has involved such widely diverse diseases that economic factors alone cannot provide an adequate explanation. As compared with the first six months of 1930, deaths from tuberculosis decreased 20 per cent and the pneumonia death rate fell from 116.5 per 100,000 to 92.2 per 100,000. The death rate from diphtheria declined to less than one-half its former level and deaths from meningococcus meningitis decreased 77 per cent. Only deaths from cancer showed a slight increase, rising to 72.3 per 100,000 from 70.3 per 100,000. The rate for heart disease remained the same at 147 per 100,000. All important causes of death except the two last mentioned showed significant decreases. If this condition continues Detroit will have the lowest death rate in 1931 that that city has ever had. It is evident that the lowered mortality occurred throughout a wide range of infectious, and therefore preventable, diseases. In part, at least, hospital wards are poorly filled because there are fewer people ill, and the most important reason why there are fewer people ill in 1931 is that medicine is intrinsically altruistic. For the period reported upon, the death rate for typhoid fever for Detroit was but 37 per 100,000, approximately one in 300,000. As compared with conditions of fifty and sixty years ago the saving for health and life from this one disease will explain not a few empty hospital beds.

Abstracts

Traumatic Military Tuberculosis By JEAN FIRKET (Rev belge des Sci méd, 1931, III, 532-547)

Two illustrative cases furnish the basis for a discussion of the pathogenesis and medico-legal significance of military tuberculosis following trauma. In one instance a young man died 21 days after receiving a severe blow upon the head. At autopsy an active tuberculous meningitis with scattered military tubercles in lungs, spleen and kidneys was found. An old cascating focus was found at the hilus of the right lung. In the other case there was chemical trauma to the respiratory tract by the inhalation of ammonia. Death occurred 12 days later. Young military tubercles and early exudative foci were found in the lungs, spleen, kidneys and meninges. There was an old hilus lesion. It was decided that these two cases could properly be considered examples of traumatic military tuberculosis. It is suggested that the following points must be established before admitting a causal relation between trauma and the development of a military tuberculosis:

1. The reality of the accident,
2. That the clinical symptoms and particularly the fever did not appear until some days after the trauma,
3. That there were no clinical evidences of the development of a tuberculosis before the traumatism,
4. That the diagnosis of military tuberculosis was confirmed at autopsy, and the distribution of the lesions found to correspond with the clinical signs,
5. That a culture of recently active tubercles from the lesions was obtained.

BAUMANN and C. SCHILLING (Klin Wchnschr, 1931, x, 1249-1252)

The principle of contrast demonstration proposed by Radt and investigated also by Oka is the basis of the present study. In this method the contrast substance introduced in colloidal state into the organism parenterally, is taken up by the reticulo-endothelial cells in finely granular form. In further study of this method the authors made use of a preparation containing 25 per cent thorium dioxide (ThO_2) which was miscible with all body fluids without precipitation. It was found that 1 cc of this 25 per cent thorium dioxide preparation was sufficient to produce a positive shadow of liver and spleen in a 2 kgm. rabbit. The shadow reached its maximum depth in two hours. Through further injections and in larger amounts (3 cc twice a day until 12 cc had been given) a much deeper shadow resulted. Histological study of a few animals showed very fine glistening particles in the reticulo-endothelial cells. After twenty-four hours the Kupffer's cells of the liver were found greatly swollen and in a rabbit which had received 12 cc of the thorium preparation they were as large as liver cells fourteen days after the last injection. There was no necrosis of liver cells found. This method was made use of successfully in studying the effect of drugs upon the size of the spleen and liver in rabbits and dogs.

Studies in Asphyxia. I. Neuropathology Resulting from Comparatively Rapid Carbon Monoxide Asphyxia By JOHN CHORNEY and R. R. SAYRE (Public Health Reports, 1931, XLVI, 1523-1530)

It has been repeatedly observed that cases of carbon monoxide poisoning have a fatal termination even though respiration has been restored and the carbon monoxide removed from the blood. The series of experiments, of which this is the first report

have in view obtaining fundamental information as to the response of the animal organism to such an asphyxial environment, looking toward devising a therapeutic procedure for apparently moribund cases of carbon monoxide poisoning. This first study deals with the neuropathology found in four dogs after continuous exposures of 20 to 30 minutes to 0.6 per cent carbon monoxide by volume in air. These conditions produce 75 to 85 per cent carbon monoxide hemoglobin and result in death at the end of the period of exposure. The changes found in these animals were fairly constant and were lacking in control material. The brain, as a whole, showed a severe perivascular and perineuronal edema. This was most marked in the corpus striatum, the cortex, and the dorsal motor nucleus of the vagus nerve. Congestion was marked throughout and there were a few petechial hemorrhages in the corpus striatum and cortex. A few lymphocytes and leucocytes were found in the perivascular spaces. Many nerve cells were swollen, distorted and vacuolated and showed marked changes in the Nissl material. Some cells were shrunken and stained diffusely while others showed varying degrees of chromatolysis. The most serious lesion produced by this type of asphyxia appeared to be the edema of the dorsal motor nucleus of the vagus and the adjacent area in the medulla oblongata.

Insulin Resistant Diabetes By MARCEL LABBÉ (Rev belge des Sci méd, 1931, III, 465-491)

Those paradoxical cases in which insulin fails to give the usual effects and which are spoken of as "insulin-resistant" appear to be frequent to some observers and rare to others. A majority of the published examples of insulin resistance represent errors in interpretation growing out of poor management in connection with insulin therapy. True insulin resistance exists but it is rare. It appears in an incomplete form in certain endocrine diabetics, and in a complete form in certain cases of insular diabetes without

any known explanation. Its existence may be established, (a) if in a diabetic on a suitable régime insulin fails to depress the level either of glycosuria or ketosis, (b) if in a diabetic who is adhering to a suitable régime excessive amounts of insulin are required to prevent glycosuria and acidosis, and to maintain nutritional equilibrium, or (c) if the sub-cutaneous or intravenous injection of insulin in the amount usually employed to demonstrate a hypoglycemia fails to lower the level of glycemia to the degree usually seen in the diabetic. Rigid application of these criteria will make it possible to exclude the false examples of insulin resistance and to recognize the true condition in both its incomplete and complete forms.

Effect on Life Insurance Mortality Rates of Rejection of Applicants on the Basis of Medical Examination By ROLLO H. BRITTON (Public Health Reports, 1931, XLVI, 46-62)

In connection with a joint investigation on occupational mortality by the Actuarial Society of America and the Association of Life Insurance Medical Directors data were secured on ordinary insurance business during the years 1915 to 1926, involving more than one-half billion dollars in death claims. Analysis of this large mass of information suggests that the insurance medical examination results in a lower mortality during the earlier insurance years as compared with persons of the same age who have held policies for a longer time. The duration of this selective effect appears to last for three or four years for all causes, except possibly at the highest age levels. For tuberculosis and heart disease it is possible that the selective effect is of much longer duration. The mortality rates in the first years of policy life are only about two-thirds of those after the effect of selection has disappeared. These results would seem to have an important and positive bearing upon the question of the value of periodic health examinations.

Reviews

Physical Diagnosis. By WARREN P ELMER, B.S., M.D., Associate Professor of Clinical Medicine, Washington University, School of Medicine, Assistant Physician to Barnes Hospital, Physician-in-Charge Missouri Pacific Hospital; Consulting Physician to Jewish Hospital, St Louis and W D. ROSE, M.D., Late Associate Professor of Medicine in the University of Arkansas, Little Rock, Arkansas. 903 pages, 337 illustrations The C. V. Mosby Company, St Louis, Mo., 1930 Price \$10.00

This book is a very complete revision of the work by W. D. Ross on the same subject. There has been a rearrangement of the subject matter with a division between the technic and the findings in the physical examination of the normal body (Part I, 530 pages), and the physical diagnosis of disease (Part II, 338 pages). This difference may be clearly understood if Part I be thought of as General Physical Diagnosis in contrast to the Special Physical Diagnosis of Part II. Throughout the first division there are numerous references to pathologic conditions and the technic of eliciting those physical signs which are produced only in pathologic conditions is also included in this section. Of necessity, since this is a textbook suitable for use in medical schools, the level of approach is that of the second year medical student. Nevertheless the more advanced student, the intern, and the practitioner will find this book of very great value. The reviewer feels that it should not be necessary to include such information as that the heart has two auricles and a ventricle or that the lungs have lobes and that the left auricle is smaller than the right auricle, while the right auricle is larger than the left auricle.

lung as given (page 62) is less than one-half that known to exist at the present time. Taken as a whole, however, this is a very useful and very well written book. The illustrations are extremely well chosen. They show precisely how certain procedures are to be carried out. Surface relations are illustrated by both photographs and skeletal charts arranged in pairs in a very instructive manner. No opportunity is lost to teach clinical pathology on practically every page.

Selected Readings in the History of Physiology By JOHN FARQUHAR FULTON, M D, formerly Fellow of Magdalen College, Oxford, Sterling Professor of Physiology, Yale University. xx + 317 pages, 60 illustrations Charles C Thomas, Springfield, Ill, and Baltimore, Md, 1930 Price, \$5.00

This interesting work is a source book for the history of Physiology. Eighty-five selections have been chosen from original sources and are presented in the original English, if the text first appeared in that language. Otherwise contemporary English translations are used where such exist. Each is preceded by a brief explanatory note, in part biographical and in part indicating the significance of the work quoted in connection with contemporary knowledge. The selections chosen are grouped in eight main divisions or chapters, corresponding to the usual divisions of didactic Physiology. Within each group the arrangement is chronological. The choice of the individual readings might well be a subject for discussion among physiologists and medical historians, less in respect to the investigators included as to whether the paragraphs selected are the most important or the most significant among their writings. Individual viewpoint will reflect itself in a certain degree. To the student of the history of physiology, in a direct

matter and in literary value Interest is well sustained throughout The illustrations are not the familiar ones from medical histories, and the liberal use of reproductions of title pages will appeal to the book lover. This book should be read by every medical student as collateral reading in the second half of his course in physiology Many practitioners will appreciate it and it should be a popular gift book among a large group interested in the biological sciences

Protozoan Parasitism of the Alimentary Tract Pathology, Diagnosis, and Treatment By KENNETH M LYNCH, M D, Professor of Pathology, Medical College of the State of South Carolina, Charleston, South Carolina xviii + 258 pages, 37 illustrations The MacMillan Company, New York City, 1930 Price, \$3.75

To serve as a connecting link between systematic protozoology and clinical medicine in respect to the protozoan parasites of the alimentary tract is the purpose of this monograph The author properly recognizes that most practitioners of medicine are concerned only with the pathogenic significance, recognition and treatment of a limited number of important parasites Technical descriptions, such as the professional protozoologist would require, are largely omitted or rewritten in a manner understandable to those doing medical laboratory work Procedures are outlined for routine stool examinations Especially to be commended are the strongly put warnings against assigning unwarranted importance to fairly constant protozoan inhabitants of the intestinal tract when scientific evidence of pathogenic significance is lacking More carefully systematized descriptions of gross and microscopical pathology would be useful The claims of Kofoid and his associates in respect to finding *Endamoeba histolytica* in the tissues of joints in

arthritis deformans and in the lymph nodes in Hodgkin's disease are properly discredited Treatment is fully outlined in respect to those organisms known to be pathogenic This book will correct many false impressions which are commonly held

Discovering Ourselves, A View of the Human Mind and How it Works By EDWARD A STRECKER, A M, M D, Professor of Nervous and Mental Diseases, Jefferson Medical College, Philadelphia, and KENNETH E APPEL, Ph D, M D, Assistant Professor of Psychiatry, School of Medicine, University of Pennsylvania xiii + 306 pages, 28 illustrations The MacMillan Company, New York City, 1931 Price, \$3.00

This is a book for the individual, about himself, and it is a book with a mission Although it deals with the fundamentals of normal and abnormal psychology, it is never abstruse, or unclear, or dull It can be read by every medical man and every intelligent layman, too, with pleasure and profit It succeeds in avoiding the specialized terminology of psychology, substituting well understood and yet scientifically accurate expressions for the vernacular of the specialist. The authors thus state their objective "If the stakes in the game of physical hygiene are health and life, then the stakes in the game of mental hygiene are even higher, efficiency or inefficiency, success or failure, happiness or unhappiness, replete, satisfying, and worth while lives or empty, unsatisfactory, and pathetic existences, sanity or insanity It is to the realization of the constructive potentialities of the human mind that this book is dedicated" The physician who has a sympathetic grasp of its content will find that he can prescribe this book with profit to certain of his patients

College News Notes

The American College of Physicians began to publish an official journal, known as "Annals of Clinical Medicine", July, 1922. It is interesting to note that the following members contributed to that number.

Dr James M Anders, (Master)

Dr. Sydney R Miller, (Fellow)

Dr Leonard M Murray, (Fellow)

Dr C C. Bass, (Fellow)

Dr Louis M Gompertz (Deceased),
(Associate)

Dr. William Carpenter MacCarty, (Fellow)

Dr Leo L. Hardt, (Fellow)

Dr. Vernon C Rowland (Fellow), Cleveland, was the official representative of the American College of Physicians, appointed by the President, on the occasion of the formal dedication of the Lakeside Hospital group at Cleveland, June 7, when Western Reserve University brought to completion its \$15,000,000 Medical Center. From all sections of the country delegates of the leading scientific, medical, educational, social and civic organizations came to attend the ceremonies and pay tribute to this institution. The address of dedication was delivered by Dr. Hans Zinsser, Professor of Bacteriology of Harvard University Medical School. Later, Western Reserve University conferred upon Dr. Zinsser the honorary degree of Doctor of Science. This degree also was conferred upon Dr. David W. Hoar, Director of Laboratories, Massachusetts General Hospital, and Assistant Professor of Pathology at Columbia University; Dr. J. P. Howard, Surgeon, Dr. H. A. Henshaw, Professor of Surgery, Johns Hopkins Hospital, Baltimore, Dr. G. E. Loomis, Professor of Surgery, St. Louis University School of Medicine, St. Louis, Mo., and Dr. D. C. Peckham, Professor of Pathology, University of California, Berkeley.

Newton Richards, Professor of Pharmacology at the University of Pennsylvania School of Medicine The degree of Doctor of Laws was conferred upon Dr. Henry A. Christian (Fellow), Hersey Professor of the Theory and Practice of Physic at Harvard University Medical School, and on Dr. James Ewing, Professor of Pathology, Cornell University Medical College

Dr William Gerry Morgan (Fellow), Washington, D C, was recently elected a member of the Board of Regents of Georgetown University

Dr E J G Beardsley (Fellow), Philadelphia, gave the graduation address of the Medical Field Service School at Carlisle Barracks, Carlisle, Pa, May 30, 1931, upon "Service Ideals, the Medical Profession and the Public".

On June 17, 1931, Dr. Beardsley addressed the members of the Hazleton (Pa.) Medical Society upon "Medical Art in Connection with Cardiovascular Disorders".

Dr Frank B. Cross (Fellow), Brooklyn, on May 19, addressed the Medical Society of the County of Kings on "Stimulation of the Renal Secretion".

"What the Doctor of Internal Medicine Expects from the Occupational Therapists" was the subject of an address delivered by Dr. Walter P. Anderson (Fellow), New York, N. Y., May 22, before the Brooklyn Society of Internal Medicine.

Dr. Henry M. Moses (Fellow) Brooklyn, N. Y., read a paper on "Carcinoma of the Lung", May 12, at the meeting of the Medical Society of Bay Ridge.

Dr. William J. Keer (Fellow), San Francisco, is listed as one of the present speakers.

ers at the annual meeting of the Canadian Medical Association, June 22-26 Dr Kerr's subject was "Coronary Occlusion"

Dr Israel M Rabinowitch (Fellow), Montreal, addressed the same meeting on "Diabetes"

Dr Anton J Carlson (Fellow), Chicago, and Dr Fred Moore (Fellow), Des Moines, are members of the Committee appointed to follow up the findings of the medical service section of the White House Conference on Child Health and Protection, as announced by Secretary Ray Lyman Wilbur on May 20 Dr Wilbur is Honorary Chairman of this Committee The findings of this Committee will be distributed to those organizations that are striving to improve the health of children

Dr Thomas B Fitcher (Fellow), Baltimore, and Dr James H Means (Fellow), Boston, were elected President and Secretary, respectively, of the Association of American Physicians at its annual meeting on May 6

Dr Cyrus C Sturgis (Fellow), Ann Arbor, was elected Secretary of the American Society for Clinical Investigation on May 4

The following Fellows of the College addressed the American Heart Association on June 9, during its seventh annual meeting, in Philadelphia

Dr Fred M Smith, Iowa City
Dr Stewart R Roberts, Atlanta
Dr John H Musser, New Orleans
Dr David Riesman, Philadelphia
Dr James B Herrick, Chicago
Dr Paul D White, Boston
Dr Emanuel Libman, New York

Dr Elliott P Joslin (Fellow), Boston, recently addressed the George Washington University Medical School on diabetes

Dr William Engelbach (Fellow), New York, on June 20 addressed the Schuyler County (Ill) Medical Society on "Diagnosis and Treatment of Endocrine Disorder".

Dr Fred M Smith (Fellow), Iowa City, delivered an address on "Arteriosclerotic Heart Disease", April 9, before the Linn County (Iowa) Medical Society

Dr Jeannette Dean Throckmorton (Fellow), Des Moines, was recently elected Treasurer of the Iowa State Medical Women Society

Dr George R Minot (Fellow), Boston, presented a paper on "Adequate Treatment of Anemia" before the Plymouth District Medical Society on May 21 at Abington

Dr Paul D White (Fellow), Boston, spoke on "Precordial Pain and Tenderness" at a meeting of the cardiac course of the New England Heart Association on May 13

Dr Frank Vander Bogert (Fellow), Schenectady, used as his subject "Feeding of Sick Children" in an address, May 12, before the Medical Society of the County of Washington (New York)

Dr Lawrason Brown (Fellow), Saranac Lake, and Dr James B Herrick (Fellow), Chicago, are on the tentative program of the Oklahoma City Clinical Society, which will hold its annual fall conference November 2-5

The following Fellows of the College addressed the Garfield County (Okla) Medical Society, April 9, as indicated

Dr Porter P Vinson—"Diagnosis and Treatment of Cardiospasm",

Dr John H Musser—"Acute Infections",
Dr Charles A Elliott—"Blood Pressure"

Dr Donald R Ferguson (Fellow), Philadelphia, Clinical Professor of Medicine at the Hahnemann Medical College, was recently elected President of the Philadelphia County Homeopathic Medical Society

Dr Franklin F Murdoch (Fellow), Lieutenant Commander, U S Navy, was appointed during June, Professor of Tropical Medicine at the George Washington University Medical School

Dr Frank Vander Bogert (Fellow), Schenectady, used as his subject "Feeding of Sick Children" in an address, May 12, before the Medical Society of the County of Washington (New York)

Dr Lawrason Brown (Fellow), Saranac Lake, and Dr James B Herrick (Fellow), Chicago, are on the tentative program of the Oklahoma City Clinical Society, which will hold its annual fall conference November 2-5

The following Fellows of the College addressed the Garfield County (Ola) Medical Society, April 9 as indicated

Dr Porter P. Vinson—"Diagnosis and Treatment of Cardiospasm"

Dr John H Musser—"Acute Infections";

Dr Charles A Elliott—"Blood Pressure"

Dr Donald R Ferguson (Fellow), Philadelphia, Clinical Professor of Medicine at the Hahnemann Medical College was recently elected President of the Philadelphia County Homeopathic Medical Society

Dr Franklin P. Woodhull (Fellow), Lieke in Germany, U. S. Army, was appointed during June Professor of Tropical Medicine at the George Washington University Medical School

Dr. James Craig Small (Fellow), Philadelphia, was elected an honorary member of Phi Beta Kappa, Iota Chapter of Pennsylvania, on June 6, 1931, the twentieth anniversary of his graduation from Gettysburg College

Dr M Murray Peshkin (Fellow), New York, delivered a paper on "A Dry Pollen Ophthalmic Test in Asthma and Hay Fever Patients Negative to Cutaneous Tests", June 9, before the American Association for the Study of Allergy at Philadelphia. The technic of the dry pollen eye test and the various positive reactions in natural colors were shown in the Allergy Section of the Scientific Exhibit of the American Medical Association during the week of June 8

Dr Michael Vinciguerra (Fellow), Elizabeth, N J, was recently appointed Assistant in Neurology at Columbia University and Assistant Visiting Physician in Neurology at Columbus Hospital.

Dr Mortimer Warren (Fellow), Portland, Maine, was awarded the degree of Doctor of Science by Bowdoin College on June 18, 1931

Dr Fred M Smith (Fellow), Iowa City, was elected President of the Iowa Heart Association on May 15

Dr Alexander G Brown, Jr (Fellow), Richmond, Va, participated in the unveiling of a tablet to the honor of Dr William Brown, his great-great-great-grandfather who was the Surgeon General of the Continental Army during the American Revolution. The unveiling exercises took place June 14 at 212 S Fairfax Street, Alexandria, Va, the bronze tablet being placed on the old home of Dr Brown

Dr John A Macgregor (Fellow), London, Ont, was the recipient of the degree of Doctor of Laws, conferred by the Senate of the University of Western Ontario at the June Convocation. Dr Macgregor is Professor Emeritus of Medicine of the University of Western Ontario Faculty of Medicine.

Dr Ross V Patterson (Fellow), Philadelphia, Dean of Jefferson Medical College and President of the Medical Society of the State of Pennsylvania, received the degree of Doctor of Science from La Salle College on May 24

Dr Horton R Casparis (Fellow), Nashville, delivered an address on "Tuberculosis in Children" on May 28 at the first of four joint meetings to be held by the Medical Societies of Roane, Monroe, Loudon and McMinn Counties (Tenn).

At the recent annual meeting of the West Virginia State Medical Association, Dr Albert H Hoge (Fellow), Bluefield, was elected President. Dr Hoge will assume office on January 1, 1932

Dr Walter Simpson (Fellow), Dayton, and Dr Cyrus C Sturgis (Fellow), Ann Arbor, addressed the Pacific Northwest Medical Association, June 25-27, at Seattle on "Tularemia" and "Treatment of Pernicious Anemia", respectively

At the annual meeting of the American Climatological and Clinical Association, on May 8, Dr Louis Hamman (Fellow), Baltimore, was elected President

During the recent meeting in Philadelphia of the Association for the Study of Allergy, Dr Albert H W Caulfield (Fellow), Toronto, was elected President-Elect, and Dr Warren T. Vaughan (Fellow), Richmond, was elected Secretary-Treasurer

Dr Lyell C Kinney (Fellow), San Diego, participated in a symposium on medical economic problems, which was presented before the San Diego County Medical Society on June 9

Dr Oscar M Gilbert (Fellow), Boulder, Colo, addressed the Boulder County Medical Society, June 11, on "Coronary Sclerosis in Diabetes"

Dr Lester R Dragstedt (Fellow), Chicago, gave an illustrated lecture on "Acute

Intestinal Obstruction" before the Twelfth District Medical Society, May 26, at Fort Wayne, Indiana

Dr Frederick G Banting (Fellow), Toronto, Ont, spoke before the students and faculty of the University of Michigan Medical School, May 8, on "The History of Insulin"

At the clinic of the Kansas City Southwest Clinical Society, June 9, Dr Peter T Bohan (Fellow), Kansas City, spoke on "Intercostal Neuralgia Simulating Visceral Disease"

Dr Henry Kennon Dunham (Fellow), Cincinnati, was re-elected President of the Ohio Public Health Association on June 4

Dr John H Peck (Fellow), Des Moines, was elected one of the Vice Presidents of the National Tuberculosis Association at its meeting in Syracuse on May 11-14

Dr James B Herrick (Fellow), Chicago, member of the Class of 1888, Rush Medical College, acted as Toastmaster at the annual dinner of the faculty and alumni during the Rush Homecoming Week

Lieutenant Colonel W Lee Hart (Fellow), has been transferred from the Army War College to Omaha, seventh corps area

Captain John D Brumbaugh (Associate), has retired from the Medical Corps of the U S Army due to incapacitation from active service

Lieutenant Colonel William L Sheep (Fellow), has been assigned to Balboa Heights, Canal Zone, as has also Lieutenant Colonel Ernest R Gentry (Fellow).

The following Fellows of the College held a Clinic for the physicians of South Carolina at the South Carolina State Sanatorium, Columbia, July 29-30

Dr R P McCam, Sanatorium, N C

Dr Paul Ringer, Asheville, N. C

Dr J B Sidbury, Wilmington, N C

Dr Thomas Addis (Fellow), Stanford, University Medical School, San Francisco, has been selected to deliver the William Sydney Thayer lecture at Johns Hopkins University School of Medicine this year

At the Texas State Medical Society's meeting in May, the following Fellows were among the out-of-state speakers

Dr Clifford A Barborka, Rochester, Minn

Dr William C MacCarty, Rochester, Minn

Dr Tom B Throckmorton, Des Moines, Iowa

Dr Ralph Pemberton (Fellow), Philadelphia, is a charter member of the newly organized American Society of Physical Medicine. The aims of this organization are to improve the practice of physical medicine, promote research, encourage clinical investigation and advance the teaching of physical medicine. The Officers are

Dr John S Coulter, Chicago, President,

Dr K G Hansson, New York, Vice President,

Dr Willis S Peck, Ann Arbor, Secretary and Treasurer

Dr George Herrmann (Fellow), formerly Associate Professor of Medicine at Tulane University of Louisiana School of Medicine, will go to the University of Texas as Professor of Clinical Medicine at the opening of the fall term. His new address is The John Sealy Hospital 810 Avenue B, Galveston Texas

Dr John E Waller (Fellow), Opelika, Ala, is the author of an article on "The Germicidal and Therapeutic Application of Soaps", which appeared in the Journal of the American Medical Association July 2, 1931

Dr Waller addressed the Central Valley Medical and Surgical Association at Albany, Ga, July 15, 1931. The Association recognized the College by its address.

Dr A G Schwach (Fellow), H. H. Hays, and Dr K S Davis (Fellow), Los Angeles, Calif, are authors of "Clinical

Appendicitis" and "Atypical Bone Tumors with Presentation of Two Cases", respectively, appearing in the July issue of Radiology

Dr William Egbert Robertson (Fellow), Philadelphia, was one of the speakers at the dedication of the Quakertown Community Hospital, Quakertown, Pa, on June 21. The hospital was erected at a cost of \$200,000, raised by public subscription

Dr Elmer Funk (Fellow), Philadelphia, was Toastmaster at the Alumni Dinner of Jefferson Medical College, July 3, when a large number of the Alumni celebrated the 160th annual Ex-Interns' Day and Alumni Day. Dr Ross V Patterson (Fellow), was one of the speakers, and, as Dean of Jefferson Medical College, accepted an oil portrait of Dr John M Fisher, Associate Professor of Gynecology, the oldest ex-intern of Jefferson Hospital

Among Fellows of the College who have recently been appointed to the Abington (Pa.) Memorial Hospital are the following

Dr Henry L Bockus, Professor of Gastro-enterology of the University of Pennsylvania Graduate School of Medicine,

Dr John Eiman, Assistant Professor of Pathology, University of Pennsylvania Graduate School of Medicine,

Dr George Morris Piersol, Professor of Medicine, University of Pennsylvania Graduate School of Medicine,

Dr G Harlan Wells, Professor of Medicine, Hahnemann Medical College,

Dr William D Stroud, Associate Professor, Diseases of the Heart, University of Pennsylvania Graduate School of Medicine,

Dr. Harry B Wilmer, Associate Professor of Medicine, University of Pennsylvania Graduate School of Medicine

Dr Arthur W White (Fellow), Oklahoma City, Okla, is author of an article entitled "Clinical Aspects of Gastric and Duodenal Ulcer" in the July issue of the Journal of the Oklahoma State Medical Association

Doctors Claiborne T Smith (Fellow), and William Bernard Kinlaw (Fellow), both of Rocky Mount, N C, were the recipients of the Moore County (N C) Medical Society's medal for having presented the best paper at the 1930 meeting of the North Carolina State Medical Society, the medal being presented during the last annual meeting of the State Society at Durham

Dr Charles G Jennings (Fellow), Detroit, was elected Honorary President of the Medical Alumni Association of the Detroit College of Medicine and Surgery on June 18, the occasion of its 61st Reunion. Dr Jennings is the oldest graduate of the College, having been graduated in 1879

Dr Ernest H Falconer (Fellow) and Dr Hans Lisser (Fellow), both of San Francisco, were recently advanced from Associate Clinical Professors of Medicine to Clinical Professors of Medicine in the University of California Medical School

Dr Thomas B Futch (Fellow) and Dr Louis Hamman (Fellow), both of Baltimore, were among the invited speakers before the Mahoning County Medical Society at Youngstown on June 18, the occasion of its 5th annual postgraduate day. Dr. Futch delivered two addresses, one on "The Problem of Arthritis in General Practice" and the other, "Manifestations of Hyperfunction and Hypofunction of the Endocrine Glands". Dr Hamman also delivered two addresses, one on "Diagnosis of Obscure Fevers", and the other, "Diagnosis of Coronary Occlusion"

Dr Willard C Rappleye (Fellow), Dr Walter W Palmer (Fellow), and Dr Arthur F. Chace (Fellow), all of New York City, have been appointed by President Nicholas Murray Butler, of Columbia University, members of the Administrative Board of Postgraduate Studies in Medicine, to have general control of all postgraduate instruction in medicine under the auspices of the University. The New York Postgraduate Medical School and Hospital became on July 1, the Postgraduate School of Medicine of Columbia University.

Dr Waller S Leathers (Fellow), Nashville, addressed the Christian County Medical Society at Hopkinsville, Ky, June 16, on "Significant Achievements in the Field of Preventive Medicine"

Dr Leathers is Dean and Professor of Preventive Medicine and Public Health at Vanderbilt University School of Medicine. He was recently re-elected President of the National Board of Medical Examiners

Dr. Charles E. Homan, Jr (Fellow), Chattanooga, addressed the Chattanooga and Hamilton County Medical Society, June 4, on "Spastic Colon"

Dr Karl H Doege (Associate), Marshfield, Wis, addressed the Wood County (Wis) Medical Society, June 25, on "Some Aspects of Acute Rheumatic Fever"

Dr Hyman I Goldstein (Associate), Camden, N J, read a paper before the American Therapeutic Society, held at Atlantic City during June, on "Streptococcal Fautitis with Erythema Nodosum and Erythema Multiforme Exudativum Diagnosis and Treatment"

Dr H Sheridan Baketel (Fellow), Jersey City, spoke on "Present Trends in the Practice of Medicine" at a meeting of the Fifth Councilor District of the Medical Society of New Jersey, at Atlantic City, April 10th. On June 24th he spoke to the physicians of the Lehigh Valley at Bethlehem, Pa, on the "Economics of Medical Practice"

Dr Jacob M Cahan (Fellow), Philadelphia, addressed the local Medical Inspectors of Public Schools on the subject of Heart Disease in Children, presenting cases with various lesions, on June 30th, 1931

The American Congress of Physical Therapy

The tenth anniversary session of the American Congress of Physical Therapy will be held October 5, 6, 7, and 8, 1931, at the Hotel Fontenelle, Omaha, Nebraska. A preliminary program and other information can be obtained from the American Congress of Physical Therapy, 30 North Michigan Avenue, Chicago, Ill

Acknowledgment is made of the following gifts of reprints by members of the College to the College Library

Dr Clarence H Boswell (Fellow), Rockford, Ill—1 reprint

Dr Arthur C Clasen (Fellow), Kansas City, Mo—4 reprints

Dr M J Fein (Associate), Brooklyn, N Y—1 reprint

Dr Hyman I Goldstein (Associate), Camden, N J—1 reprint

Dr John F W Meagher (Fellow), Brooklyn, N Y—16 reprints

Dr Roy D Metz (Fellow), Detroit Mich—1 reprint

Dr Karl Rothschild (Associate), New Brunswick, N J—2 reprints

Dr Carl V Vischer (Fellow), Philadelphia, Pa—1 reprint

Dr George L Waldbott (Fellow), Detroit, Mich—2 reprints

OBITUARIES

*DOCTOR REYNOLD WEBB
WILCOX*

Dr. Reynold Webb Wilcox (Fellow), first President and charter member of the American College of Physicians, died at his home in Princeton, N. J., June 6, 1931; aged, 75 years

Dr. Wilcox was born in Madison, Conn. He attended the Lee's Academy for his elementary education, and graduated from Yale University with the degree of Bachelor of Arts in 1878. He received his medical training at Harvard University Medical School, graduating in 1881. He held the honorary degrees of Master of Arts from Hobart College in 1881; Doctor of Laws from Maryville College in 1892; and Doctor of Civil Law from Wittenberg College in 1915. He did post-graduate work at the New York Post-graduate Medical School and Hospital, in which institution he later became Professor of Medicine. He was formerly on the Staffs of St. Mary's Hospital (New York), Ossining Hospital (New York), Eastern Long Island Hospital (Greenport, N. Y.), Nassau Hospital (Mineola) and the New Jersey State Hospital (Greystone Park). He was the author of more than three hundred and fifty articles published in various American journals. He was also author of "Materia Medica and Therapeutics", of which ten editions were published, also "Treatment of Disease", five editions; and several other books.

He was a member of the Revision Committee of the U. S. Pharmacopoeia in 1900-1910.

His memberships in scientific societies included the Harvard Medical Society, Medical Association of Greater New York, American Academy of Medicine, American Association of Military Surgeons, Society of Medical Jurisprudence, American Association on Medical Jurisprudence, American Association for Advancement of Science, American Therapeutic Society, Connecticut State Medical Association, American Medical Association, American Congress on Internal Medicine, and others.

Dr. Wilcox, with a small group of Internists, conceived the idea of the organization of the American College of Physicians, for which they secured a charter on May 11, 1915, under the laws of the State of Delaware. He became the first President, continuing in office until 1922. In recent years, he had been more or less incapacitated in health, but maintained an active and personal interest in the activities and work of the College.

*DOCTOR ARTHUR CLIFFORD
SELMON*

Dr. Arthur Clifford Selmon (Fellow), Battle Creek, Mich., died suddenly, May 16, of chronic myocarditis; aged, 53 years.

Dr. Selmon was born near Columbus Junction, Iowa, in 1877. He attended the Iowa State Normal School, then entered the Keokuk Medical College from which he later transferred to the American Medical Missionary College, receiving the degree of Doctor of Medicine in 1902. In 1903, he began missionary work in China, Honan

Province, where he remained for ten years. For eleven additional years he was engaged in missionary work in Shanghai as Internist to the Shanghai Sanitarium. During this time, he, with the help of Chinese scholars, edited a book on "Health and Longevity", written in Chinese. This book is a contribution to the cause of disease prevention in that country where, lacking health departments, the individual was the only approach to the problem. About fifty thousand copies of this book in Chinese have been distributed. It has been translated into fifteen other languages and a translation into Arabic is contemplated.

He pursued postgraduate study in Hematology at Tulane University of Louisiana School of Medicine, and in Blood Chemistry, Physical Diagnosis and Internal Medicine at the New York Postgraduate Medical School. In 1925, he became Staff Physician of the Kellogg Company, Battle Creek, which position he held until the recent creation of the W. K. Kellogg Foundation. During the five years that Dr. Selmon was in charge of the Kellogg Company Hospital, the average lost time because of sickness or injury on the part of Kellogg employees was reduced to such a degree as to establish a record for industries of the United States. Many departments were added to the hospital under Dr. Selmon's direction, until it is now one of the model industrial hospitals of the world.

As Associate Medical Director of the W. K. Kellogg Foundation, Dr. Selmon was enthusiastically and energetically organizing the plans of carrying out the purposes of the

Foundation, including the studying of the childhood causes which are blighting influences in life later on, as perhaps in his own case, an early typhoid fever may have been a factor in his untimely death.

(Furnished by Stuart Pritchard, M.D., F.A.C.P., Battle Creek, Mich.)

DOCTOR HORACE HOWARD JENKS

Dr. Horace Howard Jenks (Fellow), Philadelphia, died July 6, 1931, of bronchopneumonia, aged fifty-three years.

Dr. Jenks was born at Ashbourne, Montgomery County, Pa., June 7, 1878. He attended Haverford College, from which he graduated with the degree of Bachelor of Arts in 1900 whereupon he entered the University of Pennsylvania School of Medicine from which he graduated in 1904 with the degree of M.D. Dr. Jenks was Associate in Pediatrics, University of Pennsylvania School of Medicine from 1927 to 1929, and Assistant Professor of Pediatrics in the University of Pennsylvania Graduate School of Medicine from 1926 to date of his death. He was Assistant Visiting Physician, 1924 to 1930, and Visiting Physician, 1930 to the time of his death, to the Children's Hospital, Visiting Physician to St. Christopher's Hospital for Children since 1927 and Medical Director of the Associated Medical Clinics since 1920.

Dr. Jenks was a Fellow of the Philadelphia College of Physicians and of the American Medical Association. He was elected a Fellow of the American College of Physicians on November 11, 1930. Other memberships included the Philadelphia Pediat-

ic Society, the Philadelphia County Medical Society, the Pennsylvania State Medical Association and the American Pediatric Society. Dr. Jenks was honored by election to office in several of these organizations. He had served as President of the Philadelphia Pediatric Society, and at the time of his death was Chairman of the Certified Milk Commission of the Philadelphia Pediatric Society. To this latter position, he brought his wealth of experience and ability as an executive and organizer which he had demonstrated so thoroughly in his connection with the Associated Medical Clinics organized and developed to a high degree of efficiency by him. Quiet in dignity and reserved in manner, Dr. Jenks had a host of friends not only among his patients but also among his colleagues and associates. In his sudden death the medical profession has lost an earnest and conscientious member, the community, a citizen of greatest worth, and his family, a husband and father whose love will be cherished forever.

(Furnished by Mym E. Siegel, M.D., F.A.C.P., Philadelphia, Pa.)

DOCTOR HARRY M. HALL

Dr. Harry M. Hall (Fellow), Wheeling, W. Va., died, June 6, 1931, aged, 53 years.

Dr. Hall was born in Wheeling and received his elementary training in the Wheeling Public Schools. He attended Western Reserve University of Medicine, from which he received the Degree of Doctor of Medicine in 1898. For many years, he was a member of the Staff and Instructor of Nurses in Principles of Medicine of the Ohio Valley General Hospital. At the time of his death, he was Director of the West Virginia Tuberculosis and Health Association and Associate Editor of the West Virginia Medical Journal. He was Councilor-at-large of the West Virginia State Medical Association, having been President of that organization in 1929-1930. He became a Fellow of the American College of Physicians on November 17, 1928. He was also a member of the Ohio County Medical Society, and a Fellow of the American Medical Association.

Observations on Rheumatic Pancarditis and Infective Endocarditis*

By W S THAYER, M D , F A C P , *Baltimore, Md*

WE now know that the endocarditis of rheumatism on which so much stress has been laid in the past is but one of the manifestations of a general process, the most important feature of which, though often not the most prominent, is the cardiac disease. This cardiac disease is a general involvement of the heart in which valvular affections, acute, subacute and chronic, often, but by no means always, play a relatively important part. Indeed in the more acute and not infrequently in the more chronic forms of the malady the changes in the muscle or in the pericardium are of graver import than the sometimes more obvious endocarditis. There are other manifestations of rheumatic fever beside those in the joints and in the heart, notably changes in vessels, skin and nervous system which are rather characteristic.

That the rheumatic process is infectious is reasonably clear. That this infection is related to certain forms of streptococci is not improbable but cannot be said to have been proven. The nesting of bacteria at the seats of the characteristic focal lesions has not been demonstrated, and the inviting hypotheses of Weintiaud, Benzançon, Swift, Coburn and others who believe that the lesions and symptoms of the rheumatic disease may be dependent

upon an allergic process like that observed in syphilis or tuberculosis are not universally accepted.

Doubtless of infectious origin rheumatic heart disease may yet be distinguished from that which we call "bacterial" or "infective" endocarditis. Here the endocarditis, focal lesions on valves, mural endocardium or the intima of a larger vessel, is the essential seat of the disease the spot at which is kept alive the infection to which, more or less directly, death is usually due.

The following observations are based largely on a study of sixty-five cases of rheumatic endocarditis with necropsy, fatal during a period of activity of the rheumatic process along with a series of three hundred and six cases of infective endocarditis of which two hundred and six came to necropsy†.

*Presented at the Baltimore meeting of the American College of Physicians March 23 1931.

†The Gibson Lectures Edmh Med Jr 1931, n s, LXXXIII, 237-265, 307-334. In this article numerous references to the literature may be found which have not been included in this communication. For further references the reader is referred to the admirable monograph of Lemierre and Deschamps *Les endocardites infectieuses diagnostic et traitement* 1930 S G Dom et Cie, 1930.

It is possible to distinguish roughly two forms of rheumatic heart disease (1) The acute malignant pancarditis occurring usually in youth with high fever, pronounced leucocytosis and general appearances which might easily be associated with an acute bacterial endocarditis. In such cases death may result within a few weeks, or, gradually, the process may become subacute and end in recovery with surprising improvement in the apparent cardiac impairment but with a resultant chronic valvular disease. Sometimes the fever pursues so regular an intermittent course and lasts so long that the picture may resemble a subacute or chronic vegetative endocarditis. (2) The more subacute and chronic forms of the disease. Here, while the onset is usually characteristic of an acute rheumatic fever, yet sometimes the arthritis, the fever, the signs of cardiac involvement may for long periods be so slight and indefinite that disease of the heart may be un-

suspected. This is especially true in early childhood.

There are certain rather distinctive features of rheumatic heart disease.

Rheumatic carditis is essentially a disease of youth and adolescence. Nearly three-quarters of our fatal instances of rheumatic endocarditis with necropsy died in the first and second decades. How striking this phenomenon is is emphasized in Chart 1. In no other form of cardiac disease is the fatal issue so common in the early decades of life. Indeed in a hospital where for years, there was no large children's ward, nearly 28 per cent of patients showing acute rheumatic endocarditis at necropsy, were under the age of 10, over 72 per cent under 20. One has but to glance at the chart to see how different are the figures in infective endocarditis.

Rheumatic heart disease is essentially subacute leading to chronic valvular disease. Nearly two-thirds of these patients dying with evidences of

acute rheumatic cardiac disease showed clinical or post-mortem evidence of pre-existing chronic valvular changes. Not infrequently where the fatal attack was supposed to be primary, clinical and pathological evidence of previous changes were found indicating what should be more generally realized, namely that the early rheumatic cardiac changes may steal on the patients like a thief in the night. Often, as Swift especially has pointed out, the fever is moderate or even absent for considerable periods of time and arthritis is trivial or absent. There were long remissions and frequent recurrences. Chills are rare. Embolic phenomena were never observed except in instances of marked myocardial insufficiency, usually in association with auricular fibrillation.

Petechiae are rare in rheumatic endocarditis. In not one of our sixty-five fatal cases were petechiae observed. Anemia as a rule was rather moderate although there was a fairly

well marked leucocytosis averaging between 14,000 and 18,000 per cu mm, very much like that in subacute infective endocarditis, (Chart 2). Albuminuria was common at the height of the disease but acute glomerulonephritis, so frequent in infective endocarditis, was not observed. Acute suppurative processes common in some infective endocarditides, were not seen.

Serofibinous pericarditis is a common and characteristic manifestation of rheumatic cardiac disease. In infective endocarditis it is unusual. Serofibinous pericarditis is characteristic of rheumatic heart disease and tuberculosis. A glance at Chart 3 in which the frequency of pericarditis in rheumatic heart disease is compared with that in the infective endocarditides is striking. (Unshadowed areas in each column represent adherent pericardium.) Pericarditis in infective endocarditis is not infrequently suppurative, never in rheumatic carditis.

CHART 2 Acute and subacute rheumatic and bacterial endocarditis. Average leucocyte counts—high and low (From Edinb Med Jr 1931, n s XXXIII 263)

Streptococcal endocarditis is that form which is most likely to be mistaken for rheumatic heart disease In 186 instances of streptococcal endocarditis unassociated with acute rheumatic changes serofibrinous pericarditis was observed in little over 4 per cent

The acute myo- and endocardial changes of rheumatism are anatomically characteristic The perivascular Aschoff bodies are generally easily to be distinguished from the relatively

unimportant areas of round cell infiltration in infective endocarditis The acute verrucose vegetations on the valves and the roughening and fibrinous exudate in the outer part of the left auricle, so characteristic of rheumatic heart disease, are associated with subjacent intravalvular and sub-endocardial inflammatory changes which are distinctive

Rheumatic endocarditis is clearly a reaction to focal subendocardial necrotic and inflammatory changes

The distribution of the valvular lesions in rheumatic heart disease is characteristic. The overwhelming frequency of involvement of the mitral, and secondly, of the aortic valves is apparent in Chart 4 which illustrates the distribution of the valvular lesions in rheumatic endocarditis compared with that in the various infective endocarditides. The relative frequency of tricuspid involvement is interesting but the tricuspid involvement, though common, is usually not extensive and is rarely seen apart from mitral disease. The similarity between the distribution of valvular lesions in rheumatic and streptococcal disease is apparent.

These figures relate only to the distribution of *acute* lesions at necropsy. Among over sixty instances of rheumatic heart disease dead with acute

valvular changes, every one showed acute or chronic disease of the mitral valves and 83 per cent of the aortic. Affection of the pulmonic valves is very rare.

Cultures from the circulating blood are usually sterile, an important diagnostic point in doubtful cases. Occasionally, streptococci may be recovered. These are usually non-hemolytic and not found in large numbers or constantly, sometimes only in anaerobic tubes. That there may be exceptions will be mentioned later.

Rheumatic endocarditis, then, is a single feature of a well defined disease picture recognizable usually clinically and anatomically.

The striking characteristics of rheumatic heart disease are its prevalence in early youth, notably in the first two decades, the frequent insidiousness of

CHART 4 Acute and subacute endocarditis. Proportional involvement of individual valves (From *Edinb Med Jr*, 1931, n s, xxviii, 253)

its onset and course, its striking tendency to chronicity through recrudescences and recurrences, its evolution into the characteristic chronic valvular heart disease, its common association with fugitive non-suppurative polyarthritis and chorea, the frequency of serofibrinous pericarditis ending in an adherent pericardium, the characteristics and distribution of the valvular, vascular and widespread myocardial changes. It is notable anatomically and pathologically for the circumstance that the non-suppurative serosities, as well as the relatively benign rheumatic endocarditides appear at the outset to be connected with subjacent periarticular, sub-endocardial or sub-pericardial changes. The process does not originate on the surface.

The most important differential clinical characteristic of rheumatic heart disease is that it leads to death through myocardial failure owing to damage to muscle, valves or pericardium resulting from the immediate effects of acute inflammatory changes or more commonly to the prolonged influence, often largely mechanical, of deformities incident to the scarring of healing lesions. Even in acute rheumatic fever with symptoms of a grave intoxication the fatal issue is usually preceded by myocardial insufficiency with dilatation and congestive failure.

In *infective endocarditis*, on the other hand, the earliest changes take place on the surface of the endocardium appearing as small, soft vegetations picked with bacteria along the lines of contact of the valves. At the base of these vegetations there is necrosis and a spreading inflammatory

process which, according to the malignity of the infection and the resistance of the individual, leads to a more or less rapid destruction of the subjacent tissues. Implantation of the infection may follow on spots where the thrombi come in contact with the neighboring heart wall. From the agitated thrombi emboli are commonly distributed by the blood current. These embolic phenomena are among the most characteristic symptoms of infective endocarditis especially of the subacute and chronic forms. Renal embolisms may be so extensive as to result in pain and obvious hematuria or they may be recognized only by occasional showers of red blood corpuscles found microscopically in the urinary sediment. Embolism of the spleen is apparent through the pain and tenderness caused by overlying peritonitis. Cutaneous and subcutaneous embolisms result in phenomena, all the way from tiny petechiae to larger ecchymoses showing a white centre and an hemorrhagic border, or larger swollen cyanotic areas which are very tender. The little tender, cyanotic spots in the pads of the fingers or toes (Osler), and the larger like areas in the soles of the feet and the hands (Janeway), are almost diagnostic*. Small longitudinal painful hemorrhages under the fingernails (Horder) are frequent. Cerebral embolism with hemiplegia is very common, and embolism of larger vessels may result in peripheral gangrene. Mycotic aneurysms are frequent.

*These, as have been pointed out by a number of observers, may be dependent on occlusion of capillaries or smaller vessels by swelling and proliferation of endothelium rather than by embolism.

The character and symptoms of infective endocarditis vary greatly according to its etiology. Infections with *Streptococcus haemolyticus*, *Pneumococcus* and *Staphylococcus aureus* are notably acute and rapidly fatal; the lesions, ulcerative and destructive. Infections with *Gonococcus* or *Staphylococcus albus* which are rare, although the lesions are almost equally destructive, are somewhat less malignant as a rule and a little less acute in their course. Gonococcal endocarditis ends sometimes in recovery. Endocarditis due to more attenuated streptococci or more rarely to the Pfeiffer bacillus pursues often a subacute or notably chronic course lasting sometimes upwards of a year.

The more acute forms of bacterial endocarditis are not often confused with rheumatic heart disease. The valvular lesions are commonly unrecognizable and excepting in those acute ulcerative affections where there is an extensive destruction of tissue, the phenomena are essentially those of a rapidly fatal acute septicemia hastened generally in pneumococcal infections, by meningitis. It is the more subacute and chronic bacterial endocarditides due, in our series of 121 cases followed to a fatal termination, generally to an attenuated streptococcus (74.1%), gonococcus (10.8%), or Pfeiffer's bacillus (7.5%), which may simulate rheumatic heart disease.

In addition to the embolic phenomena already referred to, these subacute and chronic infective endocarditides have certain characteristic features—the insidious onset, the long, moderate, remittent or intermittent fever, which, indeed, may, for considerable periods

of time, be almost absent, the gradually progressive secondary anemia, the leucocytosis of about the same or a little less intensity than that observed in rheumatic heart disease, the splenic enlargement, the Hippocratic fingers, a curious brownish-grey *café au lait* complexion (Libman), the gradual development of a glomerulonephritis, usually regarded as embolic, with the appearance of albumen and red blood corpuscles and casts in the urine, and eventually of edema and evidences of renal insufficiency. Cultures from the blood in a great majority of instances yield non-hemolytic, green-growing streptococci in gradually increasing numbers. Subacute *infective endocarditis is usually fatal* after a period of from a month or two to a year or even more.

The terminal stages are generally those of a grave septicemia. The element of myocardial insufficiency was striking in only a quarter of ninety-nine fatal cases followed to a termination. Auricular fibrillation, not uncommon in rheumatic heart disease, is rare. The distribution of the lesions is very similar to that in rheumatic heart disease, for the simple reason that subacute streptococcal and influenzal endocarditis is found generally (70 per cent of our streptococcal, all of our eight influenzal infections) on valves or mural endocardium the seat of previous rheumatic heart disease.

In two respects subacute and chronic vegetative endocarditis and subacute rheumatic heart disease are similar. (1) The distribution of the lesions, commonest on mitral and aortic valves, (2) the common sub-

acute course But while in *rheumatic fever* the intoxication as a rule is not very great, the anemia not very pronounced, and embolic phenomena are absent, in *infective endocarditis*, general constitutional symptoms, fatigue, anorexia and progressive anemia are striking and embolic phenomena are common Osler's phenomena in fingers and toes are almost pathognomonic Nephritis, rare in rheumatic heart disease, generally appears in infective endocarditis Splenic enlargement is rare in the former, the rule in the latter Cultures from the blood are usually sterile in rheumatic heart disease, generally positive in infective endocarditis

The termination of subacute rheumatic heart disease may be in death from myocardial insufficiency but is usually in recovery with the establishment or aggravation of an already existing chronic valvular lesion Subacute infective endocarditis is generally fatal, the terminal symptoms being those of a grave septicemia and nephritis Signs of myocardial failure are usually unimportant

There are certain exceptions, however, to those rules. (1) *Now and then non-hemolytic streptococci are cultivated from the circulation in rheumatic fever* Usually positive cultures are only occasional and bacteria are obtained in small numbers I have seen two instances, however, of rheumatic fever of three or four months' duration in each of which, among a number of negative results there were three positive cultures of streptococcus viridans In each of these instances, the youth of the patient 14 in one (Tredway's case*), 19 in the

other (Ruffire's case), the absence of embolic phenomena, the lack of a grave general intoxication, the absence of splenic enlargement, even in the presence of repeated positive cultures, led to a correct diagnosis; in each instance the patient recovered In neither of these cases were the arthritic symptoms important (2) Recovery from infective endocarditis is probably not altogether so rare as is generally thought On this Libman especially has insisted Few pathological anatomists and few clinicians who pass the hours that they should in the pathological laboratory are unfamiliar with the irregularly scarred and deformed valves which could scarcely be due to anything else than past vegetative endocarditis It is difficult, indeed sometimes impossible, to distinguish convalescence from vegetative endocarditis where the bacteria have disappeared from the blood, from a rheumatic heart disease This or the absence of positive blood cultures, would certainly have been impossible in Perry's† remarkable instance of gonococcal endocarditis with recovery which I had the good fortune to see on several occasions

(3) It must be remembered that in rheumatic heart disease with auricular fibrillation extensive peripheral embolisms may follow the dislodging of bits of thrombi in the auricular appendage Multiple cutaneous, renal

*T Palmer Tredway Endocarditis and pericarditis with blood stream infection of *Streptococcus viridans*, Penn Med Jr, 1930, xxxiii, 389

†Perry, M W Gonorrhoeal endocarditis with recovery, Am Jr Med Sc, 1930, clx, 599-605

and splenic embolisms under such circumstances may, as I have seen, on several occasions, give rise to a rather confusing picture. Diagnosis may indeed be impossible.

(4) Such embolisms may occur in chronic rheumatic heart disease without fibrillation from the formation of mural thrombi in the left auricle. Of this I have seen one striking example.

The distinction between infective and rheumatic endocarditis though usually easy, may be difficult. One should not forget that it may be a delicate question which, like all other clinical problems can rarely be settled by the laboratory alone. It is well to re-

member that in subacute rheumatic heart disease mural thrombi may form without auricular fibrillation, giving rise to peripheral emboli very suggestive of vegetative endocarditis, that non-hemolytic streptococci may occasionally be obtained from the blood during acute rheumatic carditis, and, now and then, on several occasions, that a diagnosis on the one hand of rheumatic carditis or on the other hand of infective endocarditis cannot be made without a careful consideration of all the evidence, that a fatal prognosis in the absence of immediately threatening symptoms need never be made in either affection.

A Theory of the Causation of Cardiac Pain*

By ALEXANDER LAMBERT, M.D., *Professor of Clinical Medicine,
Cornell University, New York City*

AN unsolved problem in medicine stands as a challenge to every physician, and cardiac pain has long stood in this position. It is therefore with peculiar pleasure, and with keen appreciation of the compliment, that I accepted your Chairman's invitation to offer you some heretical opinions concerning its causation

The most recent reviews of Angina Pectoris by Obendoeffer, Kirch and Edens express the almost universal medical belief that cardiac pain is caused by a spasm of the coronary arteries. But this spasm is an unproven theoretical assumption brought forward years ago by Nothnagel. Huchard collected over sixty explanations of cardiac pain, and in some of these it is even claimed that the pain is due to spasm or anemia of cardiac muscles, forgetting that only stimulation of nerves can produce pain.

The nervous system for the heart and its reflexes belongs to a very ancient mechanism. The heart, unlike the kidneys, does not develop segmentally, but originating in the distal portion of the head descends longitudinally. Its nervous system is derived from the autonomic nervous

system, and is obtained from both the sympathetic and cranial portions.

The efferent nerves to the heart are derived from the vagal as well as the sympathetic system, but the afferent sensory nerves belong only to the sympathetic portion. The cardiac vagal system does not carry fibers for pain, its afferent nerves carrying depressor and other vasomotor fibers. The afferent sensory fibers, passing chiefly through the stellate ganglia, join by the rami communicantes the posterior spinal nerve roots, and traversing their ganglions to the spinal cord pass upward by the spinothalamic tract through the midbrain to the centers for the autonomic nervous system in the hypothalamus in the caudate end of the diencephalon.

To appreciate clearly the ancient reflex mechanism controlling the heart, and through the break down of which pain is produced, it is necessary to review briefly some of the physiology of the autonomic nervous system, and that is best done by quoting Cannon's interpretation of it. In general the cerebrospinal nervous system furnishes the discriminative consciousness localizing internal sensation or external danger, and presiding over the action of the skeletal muscular system, makes and carries out the choice of fight or flight. Through the action

*Presented at the Baltimore meeting of the American College of Physicians, March 23, 1931.

of the autonomic nervous system, on the other hand, are furnished to the cerebrospinal nervous system, and skeletal muscles the supplies of sugar, oxygen and adrenal energy sufficient to maintain successfully the choice to fight or flee

The sympathetic portion of this system differs from the cranial and sacral portions, in that the outlying ganglia are so placed in the sympathetic portion that the nerves going through them give fibers to each successive ganglion before the nerve is finally distributed to the viscera. The cranial and sacral systems however, have their outlying ganglia in the viscera themselves. This, as Cannon points out, produces a generalized effect over all the viscera in any sympathetic discharge, while in cranial and sacral discharges of energy the stimulation can easily go to a single viscus to perform a special function without involving any other viscus. As for example, a rise of blood pressure from the general sympathetic stimulation involving the whole splanchnic system, produces a general bodily effect while the stimulation of the cranial portion to increase the tone of the intestines does not simultaneously slow the heart.

Moreover, in those viscera to which two portions of the autonomic system are distributed, the action between the sympathetic and the cranial, or sacral portions are in opposition to each other. For example, in the heart the sympathetic fibers are the accelerators and the dilators of the blood vessels, while the cranial or vagal fibers are the inhibitors of the heart action, and the constrictors of the blood vessels, and

this interchange of opposing action produces the even functioning of the heart and its instantaneous reply to varying demands for increased output.

In general it may be said of the three divisions of the autonomic nervous system that the cranial takes part with the sympathetic in the functions of respiration, circulation, digestion and absorption, the sacral portion with the sympathetic controls the elimination of the waste of the body, through emptying of bladder and rectum and those functions included in racial continuation.

The sympathetic portion secures by its general reactions the delicate balance of the body between its internal and external relations, that is, to use Cannon's phrase, in preserving the homeostasis of the body. Through its special hormone, adrenin from the adrenal glands, the sympathetic system increases and prolongs its own action.

Through this sympathetico-adrenal action the heat loss and heat production of the body is regulated, and the evenness of the bodily temperature is preserved. Through this mechanism the acid-base equilibrium is maintained, and the blood sugar for muscular exertion is prevented from falling to a dangerous degree. The circulatory adjustments, constriction of the splanchnic vessels with rise of blood pressure, acceleration of the heart, discharge of extra corpuscles from the spleen, with increased distribution of extra oxygen, and facilitation of the respiratory processes are all made by means of the sympathetico-adrenal system. Besides these physical and chemical ad-

justments, there are some nervous reflexes involving the sympathetico-adrenal system, which react intensely on the heart and general circulation. Bard has demonstrated that the center of the autonomic nervous system is located in the ventral portion of the caudate end of the hypothalamus.

Animals with their cerebral cortex removed, but with the hypothalamic center intact, still react with purposeful actions, and show prolonged periods of sham rage to slight irritations. It is evidence of emotional reaction with all inhibitions from the cortical centers removed, and the physical symptoms as in cats, of the bristling of their hair over the entire body and tail, their growling, snarling, spitting, anger, and clawing and endeavoring to scratch and run away, often with defecation and micturition, show the intensity of the general discharge from the sympathetic system. It is the evident counterpart of the blind rage of the human young in their fighting, biting, shrieking anger from a loss of cortical control. These are excellent examples of the discharge from the central nervous center, through the sympathetic system to its peripheral effectors, the skeletal muscles and viscera.

Cannon has conclusively demonstrated that any high degree of excitation in the central nervous system, whether felt as anger, terror, pain, anxiety, joy, grief or deep disgust, may rouse the sympathetic system to activity, and affect in a stereotyped fashion the functions of organs which that system innervates.

Many of the reflexes of angina pectoris and cardiac pain occur through this neural mechanism, the attacks of angina pectoris being particularly susceptible to emotional origin.

Beginning with the cardiac reflexes in the early stage of muscular exercise, it is the sudden exertion, as walking against the wind, or up a slight grade, which is often the earliest occurrence to inform a patient that his heart can give him pain. Probably the first reflex action from exertion is the increased depth and rapidity of respiration, and this is followed by a conscious reflex from the higher nervous centers, which quickens and deepens the respiratory flow. This starts the necessary supply of increased oxygen, and with the bellows effect of the chest, increases the venous flow into the heart as the skeletal muscles add their increase of blood, going to the heart through the large veins. There is a rise of capillary and venous pressure, and the Bainbridge reflex occurs in the right auricle; i.e., as the increased venous blood distends the auricle, the vagus nerves around the great veins are inhibited and the accelerators are stimulated so that the rate of the heart increases in proportion to the venous return, and the blood is hurried on through heart. The increase of CO_2 and the lack of O_2 also accelerate the heart.

The anoxemia greatly increases the coronary flow. With the general muscular exertion there is an inhibition of the splanchnic area, and a general rise of arterial blood pressure in the body. As blood pours into the ventricles, there is a stretching of the myocardial muscles, with an increased output per

beat of the heart Both the rise of aortic pressure, and the increased cardiac output greatly increase the coronary flow through the action of Anrep and Segal's coronary reflex, which is a reflex diminution of tone of the vagal vasoconstrictor fibers producing an increased coronary flow The rise of CO_2 tension and the H-ion concentration of the blood also add to the increase of the coronary circulation In normal vigorous cardiac contraction the coronary vessels are filled and emptied with each contraction of the heart, and during each beat of the heart the coronary flow varies practically between empty vessels and well-filled flowing circulation The inflow into the coronary vessels occurs only during the diastolic period, being practically stopped in vigorous healthy hearts during the systolic compression of the vessels by the myocardium These physiologic details are probably tedious to you, but their definite picture is necessary to appreciate the cause of cardiac pain, because it is through the breakdown of the normal physiologic processes that cardiac pain is produced

It is important to remember that the blood supply of the first portion of the aorta is only from both coronaries which form the vasa vasorum of this portion of the aorta, so that the blood supply of the ascending portion of the aorta and of the heart is from the same vessels

Spiegel and Wasserman have shown definitely that the pain from the aorta follows the same pathways as pain from the heart

Singer has demonstrated that eradication of both stellate ganglia makes

insensitive all cardiac and aortic tissues as far as the left subclavian artery

Dogiel demonstrated that the sensory nerve endings of the coronaries and of the aorta and of the blood vessels in general, lie in their adventitial coat

Odermatt in studying the sensitiveness of blood vessels has clearly shown that some arteries are sensitive to ligation, and small arteries more so than large ones

Bazett and McGlone have shown that puncture of the radial is more painful than that of the brachial, and that the pain is a dull aching generalized pain, difficult to locate, and difficult to bear, causing a sudden sensation of warmth with profuse sweating, sometimes accompanied by nausea, and in some individuals by a desire to defecate, and often followed by coldness, faintness and actual loss of consciousness

Odermatt found also that arteries that are sensitive to ligation are also sensitive when their adventitia is stretched or distended, that is, the stretching or distension of these same arteries produces pain, and it is by distension and not by contraction that pain arises

Spiegel and Wasserman have shown also that stretching of the aorta produces intense pain

Singer has demonstrated that an acute ischemia of the cardiac muscle is without any painful reaction in the experimental animal, and that the endocardium and cardiac muscle are completely refractory towards chemical, mechanical and Faradic irritation The pericardium and epicardium are definitely sensitive to mechanical and

chemical irritation, but Faradic irritation provokes little or no reaction. The sensibility of the coronary vessels is dependent on the intactness of the adventitia, which possesses a strong mechanical and chemical sensibility. The aorta is always but feebly sensitive to Faradic irritation; it is only mildly sensitive to chemical inflammatory irritations, but to mechanical pinching and pulling and stretching, the aorta is strongly sensitive. Here also the sensibility depends on the anatomical intactness of the aortic adventitia, but sensitiveness to pain on the part of the media and intima of the aorta could not be demonstrated.

Clinically we are aware that sudden rises of blood pressure may be accompanied or followed by an attack of cardiac pain. Cardiac pain is, however, not dependent alone on blood pressure, for pain occurs with low blood pressures, or with high blood pressures, and Bayliss has definitely stated that the stimulation of any afferent nerve, except the depressor nerve of the heart, will cause this rise of blood pressure. The depressor nerve rises from the heart and aorta, and passes up to the vagus. There is a good deal of discussion as to whether or not this is present in human beings, but the work of Vitti shows definitely that in the majority of mankind this nerve is present, and passes upward separately or in the main stem of the vagus to the superior laryngeal nerve. Its function is to regulate the blood pressure by bringing about a general fall of pressure, and to reduce the blood pressure when it rises to too great a height.

Clinically cardiac pain arises after the period of healthy athletic youth has passed, and the degenerations of senescence have begun, when the heart and its vascular system have become permanently damaged, when the heart has lost its power of instant vigorous response, and its ability to regain its normal functional vigor. It is in this period of senescence in the fifties and sixties that angina usually occurs. If it occurs earlier, it is through premature disease of its tissues, and the inability of its normal reflexes to bring about the normal action and equilibrium between its muscular function, and its own vascular supply.

As the myocardium degenerates there is an increasing dyspnea on exertion, and there finally comes a time when the degenerated myocardium can not contract with adequate vigor to drive on the increasing blood coming into the heart from exertion. The myocardial muscles stretch to increase the output per beat, but can not contract with sufficient vigor to accomplish it. For a while an increased heart rate per minute may act as a substitute for increased output per beat, but there comes a time when the lack of output per beat ceases to stimulate the reflex to cause increased coronary flow, and the heart is in the condition of dependence for its coronary flow on increase of blood pressure. The degenerated muscle cannot contract vigorously enough to empty out the heart, nor clean out its own coronaries. With the incompetent cardiac muscle there occurs an increasing vascular congestion, and finally dilatation of the coronary arteries by which stretching of the adventitia is

produced from over distension of the diseased arteries, and pain is the result. This pain arises from stimulation of the afferent nerve endings in the adventitia of the coronary arteries, and the pain persists until the coronary circulation can recover itself through increased muscular action of the myocardium, or diminished inflow of blood into the heart brings relief.

When the pain arises from the first portion of the aorta, the mechanism of its causation is different. With an aortitis and diseased aortic wall, or with inflammatory processes around the vasa vasorum of the adventitia which press on the sensory nerve endings, any sudden increase of blood pressure in the aorta which some emotion may cause, which any sudden demand for increased cardiac action will produce, will cause an increased stretching of the aortic adventitia sufficient to produce pain, but not sufficient to cause reflex action of the depressor nerve to occur, and by lowering of blood pressure bring about a cessation of the stretching of the adventitia. The giving of the nitrites instantly produces a general fall of pressure, a general relaxation of the vascular muscularis, and the painful stretching ceases. The action of the nitrites is substituted for that of the depressor nerve.

Clinically in attacks of angina pectoris the pain is accompanied with symptoms from widespread reflexes. There is at times lacrimation, salivation, pupillary dilatation, general intense sweating, nausea, and vomiting, or intense belching of gas. There is not infrequently a desire to micturate, and Olser and others report testicular

pain. The observations of Bazett and McGlome already quoted, demonstrate that the aching pain from arterial puncture is often followed by similar reflexes, such as a sudden sensation of warmth followed by sweating, and then coldness, faintness and even loss of consciousness. In some individuals there may be nausea at times, and a desire to defecate.

The analogy of the clinical picture of certain attacks of coronary thrombosis and the sequence of reflexes from arterial puncture is apparent. It would also seem to indicate that the pain of angina, as well as of coronary thrombosis, is of vascular origin originating in the afferent nerves of blood vessels, passing to the general autonomic center in the hypothalamus. The intensity of the pain causes an intense general sympathetic discharge producing a reflex action in both the cranial and sacral portions of the autonomic system. The pain simultaneously manifests itself through the afferent connections of the sympathetic system with the cerebrospinal nerves, being felt and localized in cortical consciousness as present in the familiar positions on the trunk and down the left arm. These widespread reflexes produced by the diffused discharge of the sympathetic system indicate how ancient is the mechanism of the cardiac pain, and to explain it satisfactorily we must consider the nervous mechanism of the heart before the neopallium was present.

The theory here offered is further supported by the results from the operations of sympathectomy performed to eradicate the pain in angina, or the occurrence of the whole anginal

symptom complex. Hesse reviewing 135 cases of various methods of sympathectomy, concludes that extirpation of the superior cervical ganglion was successful in 62.57 per cent but cutting across the superior cervical ganglion just above the origin of the great cardiac nerve, and removing the cervical sympathetic cord to just above the inferior cervical ganglion, gave 80 per cent of successes. Removing the cervical chain of ganglia with the stellate ganglion was successful in only 56 per cent. Cutting off the pathway for the vasomotor reflexes in the superior cervical ganglion is therefore more successful than obliterating the afferent and accelerator fibers through the stellate ganglion. The most successful operation obliterates the vasomotor pathway, plus some of the afferent fibers, passing through the middle sympathetic nerve and ganglion, and prevents the reflex action of the general sympathetic discharge from culminating in an attack of angina.

How does this theory of vascular distension instead of vascular contracting spasm explain better the puzzling clinical manifestation of cardiac pain? Cardiac pain is brought about by increased muscular exertion as we have just shown. It is also produced by going into a cold room or getting in between cold sheets. Cold produces contracting of the skin vessels, a sudden increase of blood pressure, a stimulation of the sympathico-adrenal action with adrenin secretion and acceleration of the heart action with quickening of the metabolism to increase heat production. Cold therefore produces increased cardiac demands for which the myo-

cardial muscles may be inadequate, and pain occurs as above.

In pernicious anemia, or in other severe anemic conditions, cardiac pain sometimes occurs. In anemia the coronary circulation is at times increased five fold above normal, but the myocardial muscles suffer in their nutrition. The diseased coronaries are already distended with blood, and with an inadequate myocardial contraction pain is all the more quickly produced. But following blood transfusion the pain ceases, because the coronary flow returns to normal proportions and with a better nourished myocardium, improved in the vigor of its contraction, the coronary distension ceases, and cardiac pain disappears.

Following acute infectious diseases such as influenza there is an acute myocardial degeneration in a subject with diseased coronaries, and there is an acute myocardial breakdown producing the coronary distensions and pain.

The cardiac pain following nicotine intoxication apparently arises from paralysis of the synapses between the preganglionic sympathetic fibers and the postganglionic fibers in the sympathetic ganglia.

Woolhard has brought forward evidence showing that the sympathetic nerve fibers alone supply the ventricular muscles. The sympathetic accelerators influence the conductivity of the cardiac impulse and the contractility of the muscles. When the nicotine poisoning is sufficiently intense there is paralysis of the accelerators which produces the same inadequate myocardial contraction as degeneration of the muscle. When the nicotine is removed the pain ceases. The use

of tobacco in some patients increases the frequency and intensity of the anginal attacks, as the accelerator paralysis is added to the already existing myocardial degeneration

Anger, fear, joy or pain, or any intense emotion, causes, as we have seen, an intense general sympathetic discharge from the hypothalamic autonomic center, and causes, as Cannon has shown, a secretion of adrenin and increased blood pressure and acceleration of the heart's action, which may make increased demands on an inadequately contracting myocardium, with the cycle of events as already described bringing on the undue stretching of the aorta, or the distension of the coronaries and cardiac pain

In coronary thrombosis or infarction the pain can be produced either by causing inadequate myocardial contraction, or by causing coronary distension in the obstructed blood vessel proximal to the obstruction. If there is sufficient collateral circulation in the coronaries to prevent the vascular distension, pain would not occur

The theory of cardiac pain here presented seems also to explain the incongruous pathologic anatomy found in post mortem examinations of those patients dying in an attack of angina pectoris, or those who gave a history of having suffered cardiac pain. Aortitis, especially luetic aortitis, has been found with a history of previous pain, and frequently found with a history of no pain. Coronary arteriosclerosis with distended vessels, or with thickened and occluded arteries, and with or without calcification, has been found with histories of pain and anginal attacks, and also with definite histories of no pain. Coronary thrombosis and

infarct occur also with and without pain. Aortitis with or without coronary disease and coronary disease with normal aorta has caused many discussions of the causation of cardiac pain

Luetic aortitis, beginning as it does in the vasa vasorum, more frequently seems to cause pain than aortitis from other causes. Kutchera Aichbergen emphasizes the fact that a history of pain is more frequently present with thin walled dilated coronary arteries than with the thickened or calcified vessels. The observation of the writer during the past two years seems to corroborate this opinion. Whatever the cause of arteriosclerosis, the first tissue to degenerate is the internal elastic layer which causes a strain on the muscularis, and a distension of the vessel. As Thoma showed, the thickened intima is a defense reaction to prevent the vascular distension, and to protect the muscularis. Cardiac pain occurs chiefly in the early years of senescence when the arterial degeneration has actively begun in both blood vessels and myocardium, and does not wait till the calcified processes of senility have occurred

It seems, therefore, judging from the evidence of experimental work, that cardiac pain arises in the ancient mechanism of the autonomic system originating in the sensory nerve endings of the cardiac vascular system, and in the wall of the adjacent aorta. This pain occurs when there is an abnormal distension of the adventitial coats of the aorta and coronaries, through the breakdown of reflex mechanisms to which the degenerated tissues of the aorta and myocardium are unable to respond effectively

The Insulin Coefficient, an Improved Method for the Clinical Control of Diabetes Mellitus*

By JOHN R. WILLIAMS, M.D., F.A.C.P., Rochester, N.Y.

THE diagnosis and treatment of diabetes are as yet on an unsatisfactory basis. In advanced cases the diagnosis is easy but in the border-line and doubtful groups a clinical problem is presented which is very difficult of solution. The finding of sugar in the urine to a large group of physicians is *prima facie* evidence of diabetes, although it has been clearly established that sugar and other reducing substances may be found in the urine in a number of conditions other than diabetes.

With the advent of blood chemical methods a few years ago, blood sugar assumed high importance in the diagnosis of the disease. To many physicians a high blood sugar is pathognomonic of diabetes. Adaptations of blood and urine sugar tests such as the glucose tolerance tests have been developed. These examinations as usually carried out are fraught with possibilities for serious error, harm and injustice to the patient. Every year thousands of persons are condemned to a life of dietary restriction and insulin therapy because in a casual examination of the urine a reducing sub-

stance or a sugar has been found which has no disease significance. Numbers of applicants are unfairly denied life insurance for the same reason. It is true that uncontrolled diabetics usually have a glucosuria and high blood sugars, that they also exhibit an abnormal reaction to the glucose tolerance test, but it is also true that a large number of people who have not diabetes will, on occasions, show these same phenomena to a degree which is both disconcerting and confusing. It may be said, therefore, that the prevailing criteria for the diagnosis of diabetes are not very satisfactory.

For similar reasons the guides to treatment which are employed are open to question.

Prevailing Criteria of Treatment in Various Diabetic Clinics

- 1 Fasting blood sugars
- 2 Blood sugars without reference to time of food or insulin therapy
- 3 Reducing substances in the urine
- 4 Grams of glucose per unit of insulin administered
- 5 Normal fasting blood sugar and sugar free urines.

*Presented at the Baltimore meeting of the American College of Physicians, March 21, 1931.

CHART 1

CHART 2

CHART 1 Graph showing approximate curve of insulin activity. The true curve is probably not a linear one, particularly with large amounts of insulin. Within the range of usual clinical application the curve is sufficiently accurate.

CHART 2 Each diabetic patient has a limited capacity to metabolize glucose. Glucose eaten in excess of that amount is eliminated in the urine. There is a fairly definite relation between intake and output. Unutilized glucose may be stored for several days before it is eliminated, therefore clinical observations based on single tests may be inaccurate. In this case it is assumed that the patient cannot utilize more than 120 grams. All above that amount is eliminated as urine sugar.

CHART 3

CHART 4

CHART 3 The insulin coefficient in each diabetic is fixed and constant. It cannot be increased by therapy. The ability to utilize glucose can be increased by the supplementary administration of insulin. In this suppositious case the patient is able to utilize only about 120 grams of glucose but when insulin is administered his utilization may be increased to 400 grams.

CHART 4 Blood sugar curve of a diabetic who received two doses of 20 units of insulin daily. Preceding the morning dose he would have sugar in the urine, two hours after it he would have reactions. This phenomenon was repeated in the evening. Insulin dosage which drives the blood sugar down into the reaction zone is wasted.

The blood sugar is a marked variable. While it is usually high in severe diabetes, in many cases it is often low; conversely in mild diabetes it is sometimes high. More important is the fact, which is rarely recognized, that blood sugar is merely a measure of insulin concentration or activity in the blood at the time when the specimen is removed. It is a fluctuating factor and not a constant one as is commonly assumed. Because the blood sugar is high at one hour does not necessarily mean that it will be high all day. One cannot determine the amount of food a patient can utilize in a day by estimating the blood sugar. That information must be gotten in another way, yet it is a common practice for physicians to base their dietary and insulin prescriptions on such data. In short, the blood sugar reveals the intensity of insulin in the blood at a certain time and gives information as to the balance between the previous meal and insulin activity. For this purpose it is valuable.

Qualitative tests of the urine for sugar with copper solutions is another procedure of questionable value. Some of the reagents in common use are so sensitive that they react to other reducing agents than sugar. Even when sugar is present the test is too crude to be of great service. I have seen many patients who have been instructed to follow a program of diet reduction and to increase insulin dosage until the urine became free of reducing substances to these tests. Many of these cases have not had diabetes. "Grams of glucose per unit of insulin administered" is a step in the right direction but it represents a combina-

tion of factors and does not take into consideration the insulin produced by the patient. Furthermore it creates the impression that the trouble with the diabetic is that he is not able to properly use insulin and that insulin has a variable strength in different individuals, whereas it is well known that diabetes is due to a failure of the pancreas to make insulin in proper amounts and that insulin has a fairly constant strength and so may be standardized.

"Normal fasting blood sugar and sugar free urine" as a guide to therapy are also open to criticism for reasons which have already been stated and also because, as usually employed, they may be very misleading and are not sufficiently definite. The wide use of this procedure as a guide to treatment undoubtedly has much to do with the great variety of dietary procedures in vogue.

Prevailing Methods of Treatment

1. Underfeeding Low fat. Insulin only to advanced cases.
2. High fat Insulin only to advanced cases
3. Balanced slightly restricted diet Diabetic foods Restricted insulin dosage.
4. Diet high in carbohydrates and calories Heavy insulin dosage.

That patients do fairly well on all these widely varying and opposing procedures indicates a great degree of adaptability in the diabetic.

This conflict of opinion and method, both in the diagnosis and treatment of diabetes, suggests to the critical student that more definite methods of diagnosis are desirable and that while

many plans of treatment are useful there is probably one which may be regarded as the optimum. A solution of the problem may be approached by first defining it. The following statements about the disease are quite generally accepted as facts.

Diabetes is due to a failure of the insulin function of the pancreas

There is a direct relation between the amount of insulin produced and the severity of the diabetes

The amount of insulin that an established case of diabetes can produce is quite definitely fixed

If these statements be true, why is not the correct diagnostic procedure to measure the insulin producing function of the pancreas? And if this be done, why is not the amount of insulin the patient is able to make an index of the severity of the diabetic process and a useful guide to treatment? I believe it can be done and that it is a thoroughly practical method of study. It has been employed in our clinic for three years with very satisfactory results. For its successful application it is first necessary to set forth certain

CHART 5

CHART 6

CHART 5 Blood sugar curve of a patient shown in Chart 4. When the insulin dose was reduced, divided into smaller doses and properly spaced, both the glycosuria and the reactions stopped. There was a sharp rise of 15 units in the insulin coefficient. Diabetic patients frequently are greatly helped by rearrangement of the diet and insulin therapy, as in this case.

CHART 6 Showing insulin coefficient graph of improper treatment of a child. This patient carried a persistently high blood sugar and in the endeavor to reduce it the diet was lowered and the insulin dose increased to the point where the coefficient dropped to minus 14. In other words, the patient was wasting a large amount of the insulin that was administered as well as that which he was able himself to produce. He was miserable from reactions and undernourishment. When his diet was corrected and his insulin dose greatly reduced and adjusted, his coefficient rose to 40. This is not an unusual experience with children. The blood sugar is a very unreliable guide to the total glucose metabolism of diabetes.

principles of the metabolism of the diabetic

The ability of the diabetic to utilize glucose is fairly constant but slowly declines over a period of months or years. It cannot be increased by eating more food. Insulin therapy increases it. Glucose, in excess of the capacity of the body to utilize it, is excreted as urine sugar. For a few days at a time it may be stored in excessive amounts. For purposes of clinical study it should be assumed that the body derives glucose from all

foods. In our clinic the standard method of approximating the glucose content of the diet is employed.

100 grams carbohydrate yields 100 grams glucose
100 grams protein yields 58 grams glucose
100 grams fat yields 10 grams glucose

Therefore, the glucose content of the diet for twenty-four hours, less the glucose content of the urine for the same period, equals the amount of glucose stored or utilized. If the observations cover a period of five or six days a fairly accurate measure

CHART 7

CHART 7 This group shows the insulin coefficient record of a child who began by stealing food. When he was apprehended he tried to conceal it by surreptitiously taking insulin. Several syringes and ampoules of insulin were found secreted in his clothing and room. By supplementing the extra food with insulin he made it appear to us that he was rapidly improving and that less insulin and more food was required. It will be noted that his coefficient rose from minus 15 to plus 45, an astonishing recovery. Accordingly the insulin dose was gradually reduced to the point where it was thought it was no longer needed. At this time his clandestine actions were discovered and effectively stopped by putting him in the hospital under strict observation. The sudden deprivation plunged the patient into coma. Since then he has been co-operative and for three years has been stabilized with an insulin coefficient approximating thirty.

CHART 8 This patient was taken acutely ill with lobar pneumonia. Before the onset of the infection he had an insulin coefficient of approximately 20. He was therefore severe diabetic but was so adjusted as to be practically well. With the onset of the pneumonia his coefficient rapidly dropped to minus 25, which means that larger doses of insulin were given to him, for reasons unknown, were not effective. The action of the pneumonia was neutralized or partly destroyed, hence the minus coefficient. The fifth observation on the day the fever terminated by crisis, the coefficient rising to plus 15. After recovery was speedy and the index rose to its former level of 20.

CHART 8

of the ability of the body unaided to utilize glucose will be afforded. The foregoing is essentially accurate if the amount of food ingested is not greatly in excess of the capacity of the patient to metabolize it. Therefore, the first step in the problem is to determine the glucose utilization.

The chief action of insulin is the formation of glycogen from dextrose. One unit of insulin promotes the utilization of approximately four grams of glucose. It is commonly

stated in the literature of the manufacturers of insulin and also by most authors that one unit of insulin will burn 15 to 20 grams of glucose in the body. For several years, in fact, since insulin has been available for clinical use we have made on highly trained, carefully controlled diabetic patients, clinical assays of the product which have been checked by independent animal experiment or assay in another laboratory. Our results almost invariably agree. It may be said, therefore, with confidence, that in the uncomplicated well controlled diabetic one

CHART 9

CHART 9 This patient, a male of 28 years, is a severe diabetic with an insulin coefficient of approximately 25. Was taken acutely ill with abscesses and osteomyelitis involving the leg. He was admitted to the hospital in profound coma. 130 units of insulin on the day of admission apparently had little effect on his diabetes. He had a coefficient of minus 130. For several weeks he suffered from large abscesses in various parts of his body. The osteomyelitis in the leg became so severe that death seemed inevitable. Leg amputation was repeatedly urged by counsel. A slowly rising insulin coefficient suggested that the infective disease process was being overcome so operation was deferred. Shortly thereafter the patient made a most miraculous recovery, justifying our faith in the method. The patient within a period of six weeks gained forty pounds in body weight.

CHART 10 Insulin coefficient graph of a renal diabetic. This peculiar disturbance is frequently treated by strict diets and insulin therapy with distinct harm to the patient. Because traces of sugar were frequently found in the urine for two years this patient was subjected to a rigorous diet and excessive insulin therapy. She was confined to bed for weeks constantly ill from reactions which took the form of a mental disturbance. With discontinuance of the insulin and proper arrangement of diet, the patient's coefficient rose from minus 40 to over 100. In a few weeks she was completely restored to health and has remained so over a period of two years. The writer has seen two cases where mild mental disturbance was directly ascribable to insulin reactions.

CHART 10

unit of insulin promotes the utilization of four grams of glucose. It is not claimed that the function of insulin action follows a linear curve. In all probability it does not. With very large doses the ratio of activity declines, but within the range of clinical application and under ordinary conditions it is approximately accurate.

The maximum amount of insulin which a patient may produce in twenty-four hours is designated as the insulin coefficient. In uncomplicated diabetes it is fairly fixed. After a permanent diabetic state is established it rarely fluctuates more than five units. From year to year in well con-

trolled cases it shows very little change.

Example of Test Case

Diet glucose	160 grams
Urine glucose	<u>40</u> grams
Glucose utilization	120 grams
$\frac{120}{4} = 30$ units insulin required.	

After studying several hundred patients in this manner the following classification was made on the basis of severity of the diabetic process

Insulin Coefficient of

Normal individual	100 +
Borderline diabetic	75 —
Mild diabetic	40 to 75
Moderately severe	25 to 40
Severe	20 or less

CHART 11

CHART 12

CHART 11 Non-diabetic suffering from a mild psychoneurosis associated with the menopause. Treated for several months on a low diet and large doses of insulin. Erroneous diagnosis based on the occasional finding of a reducing substance in the urine which had no relation to carbohydrate metabolism. Patient was instructed to increase her insulin dose gradually until the urine became clear. Suffered constantly from reactions. Her insulin coefficient under proper dietary regulation rose from minus 15 to over 100 when the tests were discontinued.

CHART 12 This is the insulin coefficient graph of a non-diabetic with a mild gall bladder disturbance. The patient was treated for one year in an institution on a low diet and large doses of insulin. She suffered constantly from reactions. She has a coefficient above 100. The erroneous diagnosis was based on the occasional finding of a reducing substance in the urine and a questionable blood sugar determination. It will be observed that with proper arrangement of her diet, her coefficient rose from minus 10 to approximately 100. Indeed, the maximum was not reached because of the unwillingness of the patient to eat the excessive food required for the test.

The average normal individual eats a diet which will yield from three hundred to four hundred or more grams of glucose. The amount will vary with the eating habits. The diet of the average temperate eater which will include sugar, bread, cake, fruit, and the common vegetables rich in starch will yield about three hundred grams of glucose. The border-line diabetic who practices little dietary restriction and who is difficult to diagnose usually eats about this amount of food. Such a diet would require seventy-five units of insulin. An individual whose coefficient is less than seventy-five should be regarded as a diabetic. Yet for purposes of diagnosis it is often desirable to carry the diet up to the point where 100 units would be required. It is confidently believed that examinations of this sort, carried on over a period of days or even weeks, in which the insulin coefficient of the individual is carefully determined, is infinitely more accurate and valuable than such unnatural tests as the glucose tolerance, or the taking of sporadic blood and urine tests after special meals. In this connection the fundamental definition of diabetes should be borne in mind. It is a disease in which the ability of the body to utilize glucose is partly lost due to a failure of the pancreas to make insulin in sufficient amount. It is not necessarily a disease of high blood sugar or urine sugar. These are incidental phenomena which commonly occur in diabetes but, also, in other maladies. The real tests are glucose utilization and insulin production.

For purposes of work in our clinic we use the following symbols

$$\begin{aligned} \text{Glucose utilization} &= \text{GU} \\ \text{Insulin required} &= \text{IR} \\ \text{Insulin administered} &= \text{IA} \\ \text{Insulin coefficient} &= \text{IC} \\ \frac{\text{GU}}{\text{IR}} &= \text{IR} \\ \frac{4}{\text{IR}} - \text{IA} &= \text{IC} \end{aligned}$$

An example of a supposititious case would be as follows

$$\begin{aligned} \text{Glucose utilization} &= 120 \text{ grams} \\ \text{Insulin administered} &= 10 \text{ units} \\ \frac{120}{4} &= 30 \text{ IR (insulin required)} \\ 30 - 10 &= 20 \text{ IC (insulin coefficient)} \end{aligned}$$

Frequently one encounters a patient who is getting more insulin than the diet requires. This produces a minus coefficient.

$$\begin{aligned} \text{Glucose utilization} &= 120 \text{ grams} \\ \text{Insulin administered} &= 40 \text{ units} \\ \frac{120}{4} &= 30 \text{ IR (insulin required)} \\ 30 - 40 &= (\text{minus}) -10 \text{ IC (insulin coefficient)} \end{aligned}$$

A minus insulin coefficient suggests a number of explanations

1. The patient may be getting insulin in too large doses which do not synchronize with the food eaten. Since insulin activity usually extends over a period of two to four hours and food digestion and absorption over from five to ten hours, excessive insulin dosage may be lost or wasted.

2. It is well known that infections interfere either with insulin production or activity.

3. Insulin injected into scar tissue may be wasted or it may leak out of the skin along the needle track.

4. The patient may be eating food in excess of that provided in the diet, thus introducing an error in the calculation.

The insulin coefficient method is a most excellent way of checking the

stealing of food which formerly was the universal sin among diabetics, and is even now occasionally practiced. Indeed, in our work we have found the insulin coefficient method of great service in detecting all kinds of errors as well as chicanery on the part of patients. By means of it we determined that a patient was not accurately measuring his insulin, his insistence to the contrary notwithstanding. We found another patient stealing insulin. This individual, a child, had purchased and secreted insulin outfits in various places and would indulge in all sorts of dietary sprees fortifying himself by the indiscriminate injection of the insulin. We have detected concealed and unsuspected infections and have used it as a clinical guide in the care of serious inflammations of various parts of the body, as bones, lungs, abscesses. In this connection it may be said that the insulin coefficient in a diabetic suffering from an inflammation is a more useful and accurate measure of the disease process than are either the leucocyte count or the temperature curve.

In the diagnosis of borderline or doubtful cases the method is particularly valuable. We have had many cases who have been under a strict diabetic regime including insulin therapy, all because traces of reducing substance were found in the urine. In some instances this reducing material was sugar, in others it was not. Many of these cases had coefficients above one hundred. They were not able to eat sufficient food to show impairment in glucose utilization. In the final diagnosis of doubtful insurance risks the method far exceeds in value and

fairness the so-called glucose tolerance test, for while it is true that all diabetics give a positive reaction to this method it is not true that all who react to it have diabetes. Furthermore there is no unanimity of opinion as to the significance of the data that is afforded. Most condemning of all, it is a wholly unnatural procedure. It falsely assumes that because the body is unable to assume a sudden and very unusual load that it is not able to perform the same work if spread over a reasonable time.

In the treatment of diabetes the coefficient method is particularly valuable. The clinician has one guiding rule. He first determines how much insulin the patient can make in twenty-four hours by a careful dietary and urine study covering several days. This becomes the patient's coefficient. If this be low, insulin therapy becomes necessary. The dosage is determined by repeated tests involving the factors of time and quantity of insulin to obtain the highest degree of glucose utilization. The constant endeavor is to raise the coefficient, for by so doing, the most effective combination of diet and hormone action is secured. In these studies it may be discovered that the patient will do best with a different arrangement of diet or insulin dosage than has been employed. Sometimes three or four small doses properly spaced are much more effective than the same number of large doses. Reactions are a sure sign of wasted insulin. In this method the blood sugar becomes a guide to insulin dosage and not to total metabolism. A quantity of insulin which produces an abnormally low blood sugar two or

three hours later is partly wasted. The patient should be kept in that state of balance which will enable him to utilize to the fullest extent the insulin which he produces himself. The body weight is an important factor in the arrangement of the diet. If the patient be undernourished then the diet should be sufficiently ample to correct this factor. If he be obese it should be modified accordingly, the constant aim being to keep the patient practically urine sugar free, with a maximum insulin coefficient and the body weight properly controlled. The method permits the epicurean patient to indulge himself with safety. The pseudo-scientific food and drug fads which have grown up around diabetes can well be forgotten.

It is not claimed that the method is infallible. There are other factors than insulin involved in the diabetic process. In the metabolism of profound coma, insulin often fails to work or acts feebly. Oftentimes in the severe diabetes of childhood insulin response is not in accord with the one to four ratio, but the method, however, is just as useful a guide to helpful therapy as if it were. The insulin coefficient offers a valuable control to clinical research on diabetes, which must be done on the human. There are many unsolved problems. For the great majority of cases, however, both for diagnosis and treatment, in our hands it is by far the best method with which we have worked.

CONCLUSION

The problem of diagnosis in advanced diabetes is simple and presents

no technical or clinical difficulties, but not so with doubtful or borderline cases. At the present time we are depending upon tests of very uncertain value, highly speculative and in a large measure illogical. If diabetes be due to a defect in the total metabolism of the individual, then tests which disclose only a slight transient or inconstant departure from the normal physiology or body chemistry and which are commonly present in other disease states, cannot be regarded as conclusive. The insulin coefficient method directly and accurately measures the capacity of the individual to utilize glucose, therefore its findings are logical and conclusive.

In like manner the criteria by which the diabetic is now dieted and treated with insulin are open to the same objections. They permit of the widest variation in therapy and are not sufficiently definite to make evident which is the best. The insulin coefficient method enables the clinician to determine with exactness the amount of insulin the patient may himself make, whether or not administered insulin is being used efficiently, and whether or not glucose is being properly utilized. Under this plan slightly elevated blood sugars and small amounts of sugar in the urine, while of interest, are of secondary importance. Its great advantage to the doctor is that he has a single guiding rule which gives him an unfailing index to the condition of the patient and for the patient it makes it possible for him to live under the best possible conditions. For these reasons it may be regarded as the optimum method.

The Effect of the Ingestion of Burdock Root on Normal and Diabetic Individuals

A Preliminary Report*

By A. A. SILVER, M.D., and JOHN C. KRANTZ, JR., Ph.D., *Baltimore, Md.*

A *ARCTIUM lappa* or burdock is a coarse biennial weed which grows in Europe, Asia and North America. Early in the nineteenth century, it was observed that the administration of burdock root was beneficial in cases of skin eruptions, gout, rheumatism and calculous complaints¹. For many centuries it has been utilized in the kitchen of many households and restaurants of the Japanese². There the root is stripped of its bark and the pulp is sliced, boiled, seasoned, and served as a vegetable much as the occidentals serve parsnips and sweet potatoes. Coincidentally it is interesting to observe that the Japanese have a high racial immunity to diabetes³. Burdock has enjoyed some reputation as an alterative in constitutional blood diseases. "Burdock tea", designated as *Radix Burdanae* in Germany, has been regarded as an efficient blood purifier. From 1830 to 1910, burdock was recognized by the United States Pharmacopeia. Culbreth⁴ lists its constituents as inulin, a bitter extract, fat, resin, levulose, and cellulose. The drug is indicated, according to this author, as a diaphoretic, diuretic, alterative, and depurative, and

is useful in gout, rheumatism and in dermal eruptions.

In 1851 Bouchardat⁵ observed that levulose was tolerated better by diabetics than glucose, and noted that patients with mild diabetes were aglycosuric when they ate 50 to 100 grams of this monosaccharide per day. Johanson⁶ showed that levulose increased the respiratory quotient more rapidly than did glucose, and that the duration of the elevated quotient was also longer. Straus⁷ recommended a daily diet of 50 to 100 grams of inulin and observed that favorable therapeutic results followed. He found also that inulin was anti-ketogenic and this seemed to indicate that this polysaccharide was absorbed. Tanaka⁸ found inulase in the placenta and in the spleen of warm blooded animals which suggests that this polysaccharide may be split in the intestinal tract by this enzyme. The work of this investigator is substantiated by the experiments of Okey⁹ who found that inulin is hydrolyzed partially by the hydrochloric acid of the stomach and that the feces of individuals fed a varied diet contains an inulin-splitting substance.

Inulin is a gamma-glucoside-fructose-ester. Krantz and Carr¹⁰ in their

*Received for publication, April 23, 1931

physicochemical investigations of the carbohydrate contained in *Arctium lappa*, have published evidence which seems to indicate that this substance has not the same degree of molecular complexity as inulin, as it occurs in the dahlia and in the tubers of Jerusalem artichoke. On the other hand, it corresponds to the inulinin isolated by Tanret,¹¹ having a molecular weight of about 1500 rather than about 5000 which is the assigned value of the molecular weight of inulin. One gram of inulin was shown by Gottschalk¹² to have a caloric value of 4.19 calories. He suggested that the usefulness of inulin in diabetes of the mild type is due to the fact that its hydrolytic product, levulose, has an insulin-enticing action. Levulose is a more labile monosaccharide than is glucose, and it may have the capacity to call forth to a greater degree than glucose, the reserve insulin of the islets of the pancreas.

Solarino¹³ showed that if dogs were fed 5 grams of inulin simultaneously or shortly before or after the ingestion of 25 grams of glucose, the hyperglycemia that resulted was less than when glucose only was given. Likewise, Ciaccio¹⁴ and Racchusa showed that inulin lowered the hyperglycemia caused by glucose in dogs. Like Gottschalk they felt that this inhibiting action was dependent upon the action of inulin on the internal secretion of the pancreas.

Recently Root and Baker¹⁵ and Carpenter and Root¹⁶ observed a patient in whose diet artichokes furnished the greater portion of the carbohydrate. Although this patient remained sugar-free on this diet, the substitution on

one day of an equivalent amount of carbohydrate in the form of baked potatoes was accompanied by a rise in the blood sugar and the prompt appearance of sugar in the urine. The resumption of Jerusalem artichokes on the next day was accompanied by a lowering of the blood sugar and a disappearance of urinary sugar.

Krantz and Carr^{17,18} have shown experimentally that in white rats powdered burdock root causes an increased storage of glycogen in the liver, and further that in dogs it is anti-ketogenic and has a protein-sparing action. These investigators considered these data to be evidence of the absorption and the utilization of this carbohydrate.

With the foregoing facts in mind the influence of the administration of powdered burdock root upon diabetic patients was observed. The first problem was the production of a food-stuff sufficiently palatable to be substituted easily for other carbohydrates in the diet. The dried root was powdered and extracted with ethereal solvents. This left a powder containing about fifty per cent of carbohydrate hydrolyzable into levulose, a small amount of fat and bitters. The remainder was cellulose. By exposing the powder to low heat, the fat and the bitters were driven off. Later, we found that by re-extracting the powder with an acetone-alcohol mixture, the fat and bitters were more completely removed. This left a powder containing sixty per cent of carbohydrate. A batter was made with 90 grams of the powder, 36 grams of butter, water, salt, saccharin, and a few drops of the fluidextract of ginger. Dividing this

into twelve equal parts and baking them as cookies, we obtained a cracker that contained approximately 45 grams of carbohydrate, 3 grams of fat, and 0.2 gram of protein

Three non-diabetic individuals who did not have evidences of disturbance of any of the other glands of internal secretion were studied. In each instance a preliminary determination of the blood sugar was made when the patient had fasted for 12 hours, and then each one was given the equivalent of 100 grams of ordinary carbohydrates in the form of Burdock root. The preparation utilized was a powder containing 80 per cent of carbohydrate, 75 grams of which were suspended in coffee, 28 grams in a flavored gelatin and the remainder in four cookies pre-

pared in the manner described. Determinations of the blood sugar were made one-half hour, one and one-half hours, two and three-quarters hours and three and three-quarters hours after the ingestion of the meal. As a control, on another day, instead of the preparation of burdock root the patients received 100 grams of carbohydrates in the form of oatmeal, canned corn, toasted wheat bread and banana and the blood sugar was estimated at the same intervals of time as in the original experiment. Chart No. II, graphs D, E and F, show the type of blood sugar curves obtained

It is apparent that when the burdock diet was fed there was a preliminary decrease of blood sugar followed by a gradual rise to just below the

fasting level at the end of three and three-quarters hours. With the meal consisting of carbohydrates other than those in burdock, a curve similar to, but less marked than that of a normal glucose tolerance curve, was obtained.

A similar experiment was carried out with known diabetic patients. To these patients we gave an amount of burdock corresponding to 33 grams of carbohydrate. On another day, under the same experimental conditions, we gave 33 grams of other polysaccharides to these patients. Similar curves were obtained with burdock, and the expected diabetic rise with slow return was obtained with the ordinary polysaccharide meal as evidenced in the following curves (See Chart No. I, graphs A, B and C).

Following the thought that there was an inhibitory factor in burdock on the hyperglycemia of glucose, the following experiment was carried out. Two known diabetics were each given the burdock and non-burdock diets as above described and blood sugars taken at the same intervals. On a third day fasting-blood sugars were taken, the burdock meal was given and followed immediately by a non-burdock meal—33 grams of each. Blood sugars were again taken at the same intervals following the ingestion of the second meal. The curves obtained indicate that there is an inhibitory effect of burdock on the hyperglycemia of glucose (See Chart No. III).

The validity of theory of Gottschalk¹² that the ketone group of lev-

ulose is capable of calling forth to a greater degree than glucose, the reserve insulin of the islets, seems to be substantiated by the foregoing results. On the other hand, however, the presence of levulose may hasten the polymerization of the blood glucose into glycogen and in this manner lower the blood sugar level.

Following this work, we began the use of burdock root in the form of crackers as above described as a substitution for the carbohydrates in the diets of several diabetic patients. In accompanying charts IV, V, VI, VII, VIII and IX we have plotted the course of several diabetic patients receiving burdock therapy. In these cases the dosage of insulin was decreased as burdock was administered.

When the blood sugar approached normal the burdock was replaced by other polysaccharides. Immediately there was a marked rise in the blood sugar which returned at once to its former level on replacing the burdock in the diet. This we found to happen in each instance where the foregoing procedure was carried out. In all cases while burdock was being administered there was no glucosuria. However, upon removing the burdock from the diet of diabetic patients and replacing it by other polysaccharides (Uneda biscuits) glucose appeared in the urine. Stool examinations on patients receiving burdock for three successive days showed no copper-reagent-reducing substances after hydrolysis with dilute hydrochloric acid.

SUMMARY

1. The carbohydrate in burdock root was absorbed and utilized by certain patients with diabetes mellitus
2. In the cases reported burdock root seems to exhibit an inhibitory action on the hyperglycemia caused by the common polysaccharides.
3. Powdered burdock root may be easily administered to patients in the form of palatable crackers
4. Mild diabetic patients may be kept at normal blood sugar levels and aglucosuric by the administration in their diets of crackers made from powdered burdock root.

Diabetes in the Negro Race*†

By EUGENE J LEOPOLD, M D, *Baltimore, Md*

IT was not so many years ago that diabetes mellitus was considered a rare disease in the colored race. In fact, it is rather common today to hear usually well informed physicians express this belief. This is not altogether surprising since the literature on the subject is indeed meager. It is hoped that such facts as I am able to present will stimulate further study of the subject.

Osler's "Principles and Practice of Medicine" until about ten years ago said diabetes mellitus was rare among negroes. I I Lemann of New Orleans was the first to call to our attention statistics which disproved this statement. In 1911¹ he published studies based upon 61,298 admissions to the Charity Hospital which showed that negroes furnished 40 per cent of the admissions to the hospital and 30 per cent of the diabetic admissions.

The incidence rate was 0.47 per cent against a white rate of 0.072 per cent. In later studies² based on 148,671 admissions during the years 1921-1927 the incidence rates had risen and were 0.34 per cent for negroes as compared with 0.23 per cent for white admis-

sions—higher for the negroes than for the white.

More recently Bowcock reported from Atlanta, Georgia, on the experience of the Grady Hospital and the Gray Clinic with diabetes mellitus in the negro. He³ found among 26,858 admissions to the colored hospital between 1921 and 1928, 112 patients with diabetes, giving an incidence of 0.42 per cent of the admissions.

Table I gives some facts concerning diabetic deaths in Baltimore⁴ for the years 1928 to 1930 inclusive. It shows that negroes formed about 18 per cent of the population of the city and had a considerably higher death rate per hundred thousand inhabitants as compared to the white population, 20.8 and 13.2 respectively. Considering the deaths from diabetes, we find 18 per cent of the population showing a rate of 18.31 diabetic deaths per hundred thousand inhabitants. The remaining 82 per cent white population had a rate of 28.66 per hundred thousand inhabitants. Roughly, for every ten deaths of diabetes per hundred thousand inhabitants among whites, 6.4 negroes died of the disease. One can therefore, no longer consider the disease as a rarity among the negroes of Baltimore. From another viewpoint the same fact becomes evident, during the past three years, ending January 1, 1931, 646 new cases of diabetes mel-

1.45% of white are diabetic

1.27% of negro are diabetic

*May be low as compared to the figures of Lemann and Bowcock because of limited intake of negro patients

litus were admitted to the Diabetic Clinic of the Out Patient Department of Johns Hopkins Hospital Table II shows that of 46,473 new admissions to the Out Patient Department 14,954 were negro patients, 31.9 per cent of the admissions. Among the 646 new cases of the Diabetic Dispensary, 189 or 28.8 per cent were negroes. These figures are somewhat lower than those given by Lemann, 40 per cent admissions and 30 per cent diabetic, and may be due to smaller proportion of negro population in Baltimore as compared to New Orleans. A study made in 1922 of 252 active cases in our clinic showed negroes to represent 22 per cent of the clinic attendance. The average white and colored incidence for the three years was 1.45 per cent and 1.27 per cent respectively. Considering individual years, white incidence was 1.33 per cent, 1.54 per cent and 1.51 per cent and colored was 0.90 per cent, 1.35 per cent and 1.45 per cent. The close approximation of the colored to white incidence may mean that the negroes have a special liking for our clinic. It is out of line with the white and negro death rates given above which show that about 60 per cent as many negroes died as did white persons per hundred thousand inhabitants. Yet it, too, points to the fact that diabetes is a rather common disease among the negroes of Baltimore.

Diabetic deaths in Baltimore in the last three years show a great preponderance of the disease among females. Table III indicates that averaging the three years, 69.2 per cent of the diabetic deaths were in females. When

TABLE III
Diabetic Deaths in Baltimore

Year	Total Deaths		Per Cent Female		Males		Per Cent Negro		Female		Per Cent Negro		Per Cent of Female Deaths	
	Male	Female			White	Negro			White	Negro			White	Negro
1927	63	133			57	6		106	114	19		177	57.2	76.0
1928	78	151			71	7		99	131	20		160	57.2	73.6
1929	54	170			50	4		80	116	19		102	54.0	80.0
Aver.													56.1	76.5

we differentiate between the white and negro deaths, we find the former comprise 56.1 per cent of all diabetic deaths and the latter 76.5 per cent.

In our series of cases in the Clinic 66.2 per cent were female, 64.1 per cent white females and 74.1 per cent colored females

The percentage of white female deaths, 54.0 to 57.2, agrees closely with Joslin's division of clinical diabetics, 55 per cent female and 45 per cent male in the middle decades of life. It is evident both from the death statistics of Baltimore and from the figures from our clinic that diabetes is more common among colored females than it is among white females

A study has been made of 100 unselected negro cases which were treated at the Clinic during the past year. In this group we find 71 per cent are females and 29 per cent males. All of the sources show that diabetes mellitus is found among negroes in a ratio of 30 to 35 per cent male and 65 to 70 per cent female. These figures are somewhat different from most of the reports on the subject. The earlier reports analyzing the occurrence of diabetes by sex were from foreign clinics and showed a preponderance of male diabetics as high as 77 per cent.⁵ Joslin found in a study of 2,646 cases occurring between 1922 and 1927, a reversal of this male preponderance and noted that 55 per cent were female and 45 per cent male. It would seem that negro females are especially prone to the development of diabetes. Bowcock has pointed out that the usual diet among negroes is especially rich in caloric values, in-

cluding such food stuffs as pork, corn-bread, fat meats, and potatoes. The tendency of the negro to live on these food stuffs produces obesity and to this the elderly female is especially prone. Joslin has pointed out that diabetes has increased in frequency even more rapidly among the older negro females than it has developed among white females of the same age group. This seems to be true in the group we have analyzed.

The study of our 100 cases by the age at which they first came under observation is shown in Table IV.

the time of the first visit to the clinic. Perhaps also the well known uncertainty of the negro as to his age may be a factor. Naturally diabetes has in the majority of instances been in existence for some years previous to the first visit. In justification of our classification, let me call attention to the lack of attention given by the negro to symptoms of the disease and the difficulty experienced frequently in attempting to obtain precise facts for the history.

A patient with a weight of ten pounds in excess of the ideal for sex,

TABLE IV
Age Distribution by Decades of 100 Diabetics

Decade	I	II	III	IV	V	VI	VII	VIII
Male	0	2	2	8	6	7	3	1
Female	0	1	2	8	32	28	4	2
Total	0	3	4	16	32	35	7	3
Per cent of 100 cases	0	3.0	4.0	16.0	32.0	35.0	7.0	3.0
Joslin 1927—White	4.6	7.0	8.8	13.0	24.0	26.3	12.8	2.6
Lemann 1928—Negro	—	—	15.5	26.8	31.0	19.7	—	—

Sixty-seven per cent of our group are found in the fifth and sixth decades as compared with 50.3 per cent in white patients as found by Joslin in 1927, and 50.7 per cent in negro patients found by Lemann in 1928. Since children up to the age of twelve years are treated in the Harriet Lane Home, we have no patients in the clinic under thirteen years of age. We have a smaller percentage of cases in the second and third decades than reported by Joslin and in the third and fourth decades than reported by Lemann. Perhaps this difference may be due to the fact that we have classed our cases according to their ages at

age, and height we have considered as obese. It may not be entirely fair to use white standards of weight for the colored race, but we know of no standards for the negro. On this basis 67 per cent of all the cases were obese, 67.6 per cent of the seventy-one females and 67.0 per cent of all the cases. Bowcock found 92 per cent of the females in his series were obese. Perhaps the negro of the more northern districts shows less obesity than in the South because his dietary habits have been modified. Yet this is not borne out. For in the age group from 40 to 60 years, obesity was present in 86.4 per cent of the cases.

Joslin has emphasized the importance of obesity as a factor in diabetes⁶ In a recent study of 1,000 cases he found 77 per cent were above normal weight It would seem that the middle-aged female negress is even more prone to fatness than is the white of the same period Besides, as Bowcock pointed out, instances of excessive overweight are far more common among the negroesses than among the white females.

Again, basing our statements upon the date of the first visit to the clinic, there are in this group of 100 cases, 19 cases known to the clinic for five years or longer The longest known is a female who came to the clinic in 1917, aged 52 years, and was placed on insulin in 1924 There is also a male, aged 41 years when he came to the clinic in 1918, who has done well on diet alone In the group of 19 there are 14 females and 5 males Two were in the fourth decade at the first visit, 6 in the fifth, and 11 were 50 years of age or older Lemann found the longest duration among those of his cases in whom onset was in the fifth decade Insulin is being taken by seven of our cases, two males and five females

It is a well known fact that syphilis is very common among negroes Lemann found⁷ among 68,004 negroes in New Orleans evidence of acquired syphilis in 56 per cent of the cases In our series every case has had the Wassermann test, both by water-bath and ice box methods Twenty (20 per cent) of these tests were positive and one test was doubtful This case was a male who gave a history of having had syphilis some years before

He had taken a series of treatments before he came to the clinic Eight other males were positive and fifteen females The amount of syphilis seen in our clinic is in agreement with the findings of Paullin, Davidson and Wood⁸ among negro patients in Atlanta, 22 per cent among Outpatient Department cases and 20 per cent of the negro hospital admissions

Warthin and Wilson⁹ have emphasized the importance of syphilis as a cause of diabetes mellitus We cannot agree with these authors since practically all of our syphilitic cases have had intensive antisiphilic treatment conjointly with their diabetic therapy.* In no instance have we been able to note any improvement of the diabetes which could not be the result of controlling their hyperglycemia by diet alone or diet and insulin We have had several cases in which blood and spinal Wassermann tests have become negative under treatment without showing any effect upon the diabetic conditions In fact, the latter has progressed as a result of inability to keep diet

Based on clinical observation with only infrequent eye examinations, 54 of the 100 cases gave evidence of hardening of the peripheral arteries beyond that to which they were entitled by age Bowcock noted this complication in 55 per cent of his cases Joslin, with more exact examinations, has found an average of all ages of 80 to 90 per cent.

We have found a systolic blood

*[Note by Editor. Antisiphilic treatment cannot be expected to remove fibrosis or sclerosis already established, or to restore island tissue]

pressure of more than 150 mm in 38 cases in which reading has been noted. This is 40.5 per cent of the cases. This is in rather close agreement with the findings of Bowcock.

The occurrence of gangrene in our series is surprisingly small. It is true that we have adopted for use in the clinic a card of directions for the care of the feet as suggested by Joslin. This does not, however, seem to be a factor in the infrequency with which we have met this serious complication in this series. Three of the four cases of gangrene showed the condition when they came to the clinic. The cases were equally divided between males and females, two each. Three of these resulted in mid-thigh amputation. The fourth suffered the loss of a big toe. Lemann noted the condition in 15 per cent of his hospital admissions which might be due to the fact that this serious complication practically always necessitates hospitalization. Another factor explaining the lower incidence is that the negroes of Baltimore are perhaps on a higher sanitary and hygienic level than those of New Orleans, and do not expose their feet as commonly to the elements which Lemann thinks helps to explain the high incidence of gangrene in his cases.

The ferric chloride test of the urine was positive in 14 per cent of our series, 10 females and 4 males. Four cases were admitted to the hospital in coma and all were rescued by insulin treatment. Lemann had 15 per cent of coma in his series.

Fifteen patients, 15 per cent, showed changes in the optic lens. There were twelve females and three males. Our

youngest case was 26 years old when a cataract was noted in his left eye and, upon his return recently, after being absent from observation for seven years another was found in his other eye. Joslin has noted cataract in about 10 per cent of his cases. Spalding and Curtis¹⁰ found it present in 13 per cent of their cases. Since the opening of the Wilmer Ophthalmological Clinic three years ago we are seeing more cataracts constantly. We had one case of bilateral glaucoma and numerous instances of retinitis and other eye conditions.

Thirty of our 100 cases have had insulin treatment, 22 females and 8 males. Lemann gave 19 of his cases insulin and Bowcock likewise. Joslin has stated recently that two-thirds of his cases are now using insulin. The smaller percentage in our series is due to several factors. We have maintained that no clinic case should have insulin unless it actually needs it. Our usual diets have contained from 60 to 80 grams carbohydrate until recently when we have increased this to 100 grams. Cost is an important factor in a group such as we have under consideration. But it does not seem that the negro has any difficulty in carrying out the systematic insulin treatment when it is necessary. It is surprising how few infections we have seen among negroes who are giving themselves the injections. In many instances they are examples of the most complete co-operation despite a meagerness of learning and lack of education. It has not been unusual in the clinic to find a negro who cannot read or write using insulin over years and keeping diet as carefully as do some

of our model white patients. Just one example is case 52, a female, aged 52, known to us since 1917, adjusted to insulin in 1924. She has taken her insulin constantly since then and has effected a 40 per cent reduction in dosage. She has never shown sugar since 1924.

All of these cases were adjusted to insulin in the hospital. We do not attempt to start a patient on insulin in the Clinic, but always give them a period of hospital study before starting injections.

Since this study is one of active cases seen during the past year, we have no deaths to report.

Economic problems occur more frequently among negro patients of an Out Patient Department than among the white cases. These are, in many cases, surmounted by efficient Social Service work. These problems concern the actual providing of diet and, when necessary, of insulin. Perhaps the greatest hindrance among the females is in their occupation as cooks. While the best of colored, as of white, cooks need not taste their cooking to be sure of its proper preparation, many cooks are not so good and must sample the food they prepare.

SUMMARY

1. Diabetes mellitus is not an uncommon disease among negroes.
2. The death rate of diabetes mellitus in Baltimore in 1930 was 28.02 for white persons and 30.01 for negroes per hundred thousand inhabitants. White deaths from diabetes were 2.36 per cent of all deaths and negro deaths were 0.96 per cent.
3. Among the new admissions to the Out Patient Department of Johns Hopkins Hospital negroes formed 31.9 per cent, and 28.8 per cent of the new admissions to the Diabetic Clinic.
4. Diabetes in the negro is even more common among females than in the white race.
5. A study of 100 cases of diabetes in the negro reveals:
 - Sex: females were about three and one-half times as common as males.
 - Age: 67 per cent of the cases were between the ages 40 and 59 years.
 - Obesity: played the major factor in etiology; 86 per cent of the older females were obese.
 - Duration: in 19 per cent of the group, the patients had been known to the clinic more than five years.
 - Syphilis: does not play an etiological factor in the cause or progress of diabetes.
 - Arteriosclerosis and hypertension were about as common as in non-diabetics of the same age.
 - Gangrene: was seen only four times in the 100 cases.
 - Acidosis: occurred in 14 per cent of the cases.
 - Cataracts: occurred in 15 per cent of the cases.
 - Insulin: was used in 30 per cent of the cases.
6. Diabetes in negroes is not different in any way from the disease as found among white people.

Syphilitic Aortitis in Retrospect*†

By WILLIAM S. MIDDLETON, M.D., F.A.C.P., *Madison, Wisconsin*

THE bedside-necropsy correlation of disease was in a considerable measure responsible for the dawn of modern clinical medicine in the late eighteenth and the early nineteenth centuries. In a majority of instances such studies can admittedly reveal only the irretrievable end products of disease; yet from such determinations it has not infrequently been possible to explain the clinical manifestations of a given entity and to discern its consecutive steps to the fatal termination. In more recent years other allied sciences have lent their impetus to the advance of clinical medicine, but the clinico-pathologic orientation still constitutes one of the most fruitful sources of the maintained growth in medicine.

Visceral syphilis has afforded an ideal field for such correlated studies, and in this direction syphilitic aortitis has received particular attention from Scott,^{1,2,3,4,5} Saphir,^{3,4} Martland⁶ and others. In the conviction that further profit must be forthcoming from similar studies, the records of the Wisconsin General Hospital have been reviewed over a period of four years. During this time twenty-one patients have succumbed to syphilitic aortitis.

Since the pathologic diagnosis has served as the ultimate criterion for the inclusion of each case in the present series, the accustomed order of affairs has been reversed and the pathologic background will be considered before the clinical analysis.

Accordingly the pertinent gross cardio-vascular findings in a typical subject (case 18) are abstracted from the report of the Department of Pathology, University of Wisconsin:

The cardiac apex lies under the seventh rib, 13 cm. to the left of the midline. In situ the heart is twice as large as the subject's clenched fist. The pericardium is smooth but slightly edematous. The pericardial cavity contains 100 cc. of clear yellowish-brown fluid. The heart weighs 623 grams. The right heart is dilated. The apex is made up of the hypertrophied left ventricle. There is a soldier's patch over the anterior aspect of the right ventricle. The several valvular rings measure as follows: tricuspid 14 cm., pulmonic 8 cm., mitral 12 cm. and aortic 10 cm. The left ventricle averages 14 mm. in thickness and the right ventricle, 9 mm. The aortic arch ranges from 7.5 to 8 cm. in circumference. The friability of the myocardium is decreased and it sections with increased resistance. The hydrostatic test proves the aortic valve to be incompetent. The aortic cusps show marked thickening at their bases with calcification. The commissures are widened. The coronary orifices show definite partial occlusion, but the several branches of the two coronary arteries show only occasional small atheromatous plaques. The thoracic aorta shows a saccular dilatation involving the last portion of the de-

*From the Department of Medicine, University of Wisconsin.

†Received for publication February 26, 1931.

scending arch Where the dilated arch impinges upon the vertebral column, there has occurred erosion of the body of the sixth thoracic vertebra on its lateral aspect The entire thoracic aorta is dilated and on section presents many atheromatous plaques, with overlying ulceration in some instances The aneurysmal sac is occupied by a dense laminated organized thrombus, which has somewhat shrunk from the wall of the same on one side and on the other aspect presents a smooth surface medially or to what was the restored blood channel Below the diaphragm the atheromatous changes in the aorta are distinctly less marked

Dr C H Bunting has kindly supplied the histologic description of the heart and the aorta

The myocardium shows hypertrophy with arteriosclerotic changes in the coronary branches There are diffuse patchy areas of myocardial degeneration, which consist of well vascularized, recently organized infarcts of microscopic dimensions Occasionally there are found small cellular masses composed of a few epithelioid and lymphoid cells without characteristic arrangement, but which might be interpreted as degenerated gummata

The sections of the aorta show marked lymphoid infiltration with a few plasma cells about the vasa vasorum in the adventitia and media The intima shows marked fibrous thickening and lymphoid infiltration While these sections of the aorta and others taken through the sinus of Valsalva show unmistakable evidences of syphilis, no gummata can be demonstrated

Turning to the clinical record the following essential notes are gleaned

The subject of this necropsy was an adult, white male 40 years of age who had been a moulder by occupation His chief complaint on admission to the hospital had been shortness of breath, which had been remarked seven weeks previously, coincident with an acute upper respiratory infection A cough which had appeared at the onset had been definitely aggravated by exertion and over-heating A week after the onset a sore aching feeling had appeared in the precordium and this sensation

had persisted up to the time of admission, as had the dyspnea In addition there had occurred a pain in the left side of the back about a year before the onset of the present trouble This pain had grown so severe that at the time of entrance the patient could not lie on the left side Sleeplessness had ensued and added to this the periodic experience of a sudden awakening at night with a profound inability to get his breath had been noted A sense of suffocation with a struggle to get air had been the patient's analysis of these episodes

The inventory by systems had failed to elaborate the above story and the past medical history had revealed no illness of significance The patient had denied the occurrence of venereal disease in any form

The social history had been deemed especially important in the occupational and marital details Born in Poland, the patient had come to America at 21 years of age His work had always been laborious as a farm hand and as a moulder Married first at the age of 27, his first wife had died one year later of an acute abdominal condition, the nature of which had been unknown to the patient There had been no issue from this marriage Three years later he had married a second time This wife remains living and well Three children by this wife are living and well, a fourth had died in infancy of unknown cause

The family history is irrelevant

The pertinent physical findings had been largely circulatory and are herein briefed Orthopnea and cyanosis had been noted The apical impulse had been noted in the left sixth interspace 12.5 cm from the mid-line Further systolic impulses had been observed in the second and third interspaces A double thrill had been palpated over the second interspaces close to the sternum to either side A supracardiac cap of dullness had been demonstrated The cardiac borders had been noted thus

Right mm	Interspace	Left mm
42	2	31
48	3	44
46	4	95
	5	126
	6	148

A loud blowing systolic and a diminuendo diastolic murmur had been audible over the entire precordium. A separate apical systolic murmur had been noted. The transmission as well as the point of maximum intensity of the several murmurs had been rendered difficult of elicitation by reason of their loudness and wide dispersion. The peripheral pulse had been ill-sustained and a well marked Duroziez's sign had been established in the femoral arteries. There had been a pronounced capillary pulse. The blood pressure had registered 160 mm of mercury systolic and 58 mm diastolic. The venous pressure had been 10 cm of water. The other signs of note had been the showers of basal congestive râles and the enlarged liver, palpable 10 cm below the costal margin.

The clinical impression had been syphilitic aortitis with aneurysm of the arch, aortic insufficiency, cardiac hypertrophy and dilatation with relative mitral insufficiency, to which had been added the evidences of decompensation in chronic passive congestion of the lungs and liver.

The laboratory findings bearing directly upon the diagnosis had been

- a—Blood Wassermann reaction +++++
- b—Electrocardiogram showing left ventricular predominance, negative T_1 and slurred R_2
- c—Roentgenologic studies repeatedly demonstrating enormous widening of the cardiac shadow particularly in the left ventricular region, increase in the aortic width with sacculation in the descending arch and erosion of the body of the sixth thoracic vertebra

The clinical course during the hospital stay had been marked by persistence of nocturnal pain. At times such attacks had been initiated by a substernal pain oppressive in nature and persistent. Occasionally a choking spell had occurred and had been accompanied by great numbers of inspiratory and expiratory wheezes and squeaks throughout the chest. Later dysphagia had become apparent. A positive centrifugal venous pulse had been noted shortly after admission and had favored the conclusion of a tricuspid insufficiency. Several syncopal attacks had marked the further progression

of this course. As a rule bloody frothy expectoration and obvious pulmonary edema had attended such attacks. Throughout the period of hospital observation the backache had constituted the one constant complaint. As a rule there had been no exact localization to the same, but it had always been left-sided and had radiated about the lower left chest, although to a lesser degree there might have occurred some radiation to the right at times. Death had resulted on the seventieth day from progressive circulatory failure.

Accordingly it would appear that every detail of the pathologic picture had been anticipated in this instance by the clinical findings and diagnosis. The nocturnal dyspnea, posterior root pains, dysphagia, and the physical and roentgenologic findings of an aortic dilatation and regurgitation with cardiac enlargement occurring in a man of 40 years could leave little doubt as to the etiologic background. The sequence of events was equally apparent. The positive Wassermann reaction was merely confirmatory. The marital history, as is so frequently the case, gave no directional information. Exception may well be taken to the choice of so full blown a case of syphilitic aortitis as a type; and it is further admitted that the division as utilized by Willis,⁷ syphilitic aortitis, syphilitic aortitis with aortic insufficiency and thoracic aneurysm has obvious advantages. None the less the cases herein considered represent end products and as such the above instance is a distinctive example.

The pathologic and the clinical findings for the entire group (21 cases) have been digested in Table I.

The heart's weight constitutes the first point of pathologic comparison. It was recorded in 17 instances, the re-

TABLE I

SUMMARY OF THE PATHOLOGIC AND THE CLINICAL FINDINGS

maining four figures having been sacrificed when the gross specimens were kept intact for museum purposes. Of these 17 hearts, 13 were from male subjects and averaged 468 3 grams (range, 250 to 787 grams). Only three of the 13 (250, 280 and 290 grams, respectively) weighed within the accepted normal limits. There were four hearts from female subjects weighing 420 7 grams on an average (range 305 to 470 grams). A single heart, 305 grams, from a female subject was possibly within the normal range.

The aortic ring circumference was recorded in 20 instances (16 males and 4 females). The average from the males was 7.9 cm with ranges from 6 5 to 10 cms, whereas the aortic ring in the hearts of female subjects averaged 7 8 cms with a range of 6 5 to 9 cms. Three males and one female showed aortic rings of normal circumference. A casual relationship might be anticipated between the dilatation of the aortic ring and the degree of left ventricular hy-

pertrophy, hence the cardiac weight. By the same token the smaller hearts might be expected in those cases where no dilatation has occurred in the aortic orifice. Therefore, in Table II the extreme weight figures for the two sexes have been taken and the measurements of the respective aortic rings placed in parallel columns.

The lack of close correlation becomes apparent at a glance. In other words there is no direct relationship between the cardiac weight and the size of the aortic orifice. The heart may be grossly hypertrophied without dilatation of the aortic ring. While in general the heavier hearts fall into the group with the wider aortic orifices, enough exceptions are noted to jeopardize any rule. The work of Saphir and Scott,^{3,4} in particular, affords the logical explanation for such exceptions in that regurgitation may readily take place through sagging aortic valves whose bases are the seat of syphilitic invasion without actual dilatation of the rings.

In only one instance (case 18) was

TABLE II
COMPARISON OF HEART WEIGHT AND AORTIC RING CIRCUMFERENCE

there involvement of the coronary orifices in the syphilitic process. Sixteen of 20 subjects (one had no note) showed atherosclerosis of varying degrees in the coronary arteries. Macroscopic or microscopic evidences of myocardial degeneration were noted in 17 cases. This figure is conspicuously high, and when the age distribution is considered, its significance will be even more apparent. In one case only (case 18) could histologic evidence of a syphilitic etiology be deduced from the cellular changes in the myocardium.

No detailed discussion of the findings in the aorta is necessary in this connection. The longitudinal striation of the intima and its distribution in the beginning of the aortic arch are important details known to every clinician. If more widespread, the diaphragm almost invariably marks its lowest extension. The nature of the syphilitic involvement of the aortic ring is somewhat less familiar, but its first description by Tripier⁸ is

exact and his accompanying cut (figure 1) completes the picture.

Mais ce qui apparait d'une maniere tres evidente dans la plupart des cas (15 fois sur 20), c'est qu'il existe entre les bords d'insertion valvulaire, contigus a l'etat normal, un écartement d'un a plusieurs millimetres que nous n'avons jamais rencontré qu'avec une altération de cette nature et qui nous semble des lors constituer pour elle un caractere pathognomonique.

To the importance of this widening of the commissures between the aortic cusps conclusive observations have been brought by Scott and Saphir,^{1,2,3,4,5} who are responsible for the present day appreciation of this detail. Sight must not be lost of the frequent overshadowing of the gross luetic picture by atherosclerosis of the aorta, and as Warthin⁶ has pointed out "when the picture is that of atherosclerosis no positive exclusion of syphilis can be made without a microscopic examination." Hence it should be borne in mind that when the gross appearance of the aorta with its atheromatous plaques and ulcerations is most

FIG 1 Widening of the commissures of the aortic valve (from Tripier)

distinctly atherosclerotic, the necessity for the histologic proof or exclusion of syphilis is even greater than when the appearance is obviously syphilitic. The criteria for a histologic diagnosis of syphilitic aortitis are embodied in the report of case 18 and they have served as the basis for inclusion of all cases in the present series. There is no necessity for reiteration of these details.

Turning to the clinical picture the social history first arrests the attention. There was only one negro in the group. As to age, 18 of the 21 individuals were under 61 years of age and 10 of the group were between 51 and 60 years, inclusive. There were 17 males and 4 females, a ratio of slightly more than 4 to 1. The severity of occupation seemingly bore little relation in predisposition in that 9 individuals followed sedentary work as compared with 12 in laborious trades.

The marital side of the social history was very illuminating. At the time of admission 5 were single, 12 married, 3 widow or widower, 1 divorced. Of the sixteen individuals sometime married, 4 were partners in sterile unions and miscarriages had occurred in 4 other couples. In other words 50 per cent of the married group had procreative disturbances.

The histories afforded but little accurate data relative to the initial lesion. In only four instances was the occurrence of a chancre admitted and the intervals in these cases were widely separated (12, 15, 25 and 40 years respectively). Of greater importance in the present relation was the subjective history of these patients

with syphilitic aortitis. Dyspnea was the outstanding complaint in 14 and it was apparently a rather late manifestation in the majority of instances. Paroxysmal nocturnal dyspnea does not occur early enough nor regularly enough to be of great help in differential diagnosis, but given the manifestation of sudden starting from sleep with a feeling of choking or of inability to breathe, syphilis of the aorta should receive first thought in explanation. Particularly is this the case when the dyspnea is so severe as to lead to fear of death. Pain was a subjective complaint in only four instances. The low incidence of this symptom is not offered as proof of its inconsequence. As a matter of fact true substernal oppression has a real bearing upon the diagnosis, but anginal attacks and posterior root pains must obviously be related to the special parts involved. Interestingly, case 18 was the only subject to show encroachment of the syphilitic process upon the coronary orifices, yet he escaped anginal attacks. It will likewise be noted that precordial oppression may occur in luetic aortitis in the absence of aneurysms (cases 6 and 10).

The diagnosis of syphilitic aortitis is simplified if aneurysmal dilatation has occurred. Pressure phenomena and characteristic physical signs render the nature and location of such a vascular sac quite exact. These circumstances will account for the diagnosis of four aneurysms of the aorta included in this series. Of the remaining 17, a diagnosis of luetic aortitis was made in 14 from the history and the physical signs without recourse to the labora-

tory As has been previously pointed out, these cases were late examples of the process Helpful signs in their recognition included suprasternal impulses, seen or felt, impulses to the right of the sternum in the second interspace, systolic shock by trans-thoracic palpation, displacement of the cardiac apex down and to the left, widening of the cardiac dullness to the left, supracardiac cap of dullness or dullness under the manubrium, peculiar "bottom of the well" quality to the aortic second sound, systolic slurring with a short rough murmur in the second right interspace transmitted slightly to the vessels of the neck, and ultimately to clear-cut auscultatory evidences of aortic insufficiency without a rheumatic or a septicemic background

A word further may be offered in explanation of certain of these signs In palpating for the aortic arch the finger should be placed in the suprasternal notch and then it should be sharply flexed as pressure is made retrosternally The patient is instructed to flex the neck In the normal (unemaciated) subject the arch of the aorta cannot be reached by this manipulation, but in syphilitic involvement with loss of elasticity of the aorta, elongation in the long axis is the first response Hence it is sometimes possible to palpate the arch by this technique before any other sign is demonstrable (Figure 2) Hoover's¹⁰ suggestion of the bimanual trans-thoracic palpation for the thrust of the elongated aorta has been largely overlooked He advised placing the right hand over the right second interspace close to the sternum and the left hand

over the left interscapular space To the palpable impulses which are frequently felt in syphilitic aortitis he applied the terms, systolic shock and diastolic impact These terms are quite descriptive However, this simple aid has frequently been neglected Innumerable qualifying terms have been applied to the aortic second sound in syphilitic aortitis *Bruit de tabouka* is a favorite, but the Algerian drum is not a familiar musical instrument to most physicians The tone has always suggested the quality of sound elicited by dropping a pebble into a well, hence the suggestion of a "bottom of the well" sound The impression gathers with the growing literature on the subject that the profession is seeking a short-cut to the accurate diagnosis of syphilitic aortitis and in the process is neglecting the time-tried and proved methods of physical examination

The laboratory does have a very important and indispensable place in the diagnosis of syphilitic aortitis Of these measures the Wassermann reaction suggests itself as the most available All patients had the Wassermann reaction studied in the blood The spinal fluid was subjected to this test in 12 cases Of the 21 specimens of blood tested there were 13 positive and 8 negative reactions whereas of the 12 spinal fluids there were 9 positive and 3 negatives A number of combinations suggest themselves, but the most helpful considerations lie in those which offer a check upon the negative blood Wassermann reactions In 6 cases with negative blood Wassermanns the spinal fluid was studied and in 3 of these it was

negative and in an equal number, positive. In 2 other instances a low titre in the blood was checked by strongly positive reactions in the spinal fluid. The present series includes a considerable number of individuals with syphilis of the central nervous system, and any evaluation of the relative importance of the Wassermann reactions in the blood and in the cerebrospinal fluid must take this detail into account. Indeed, all of the five cases in which a negative or a faintly positive blood Wassermann was paralleled by a positive spinal fluid, were diagnosed

as various types of central nervous system syphilis. Nevertheless, the check of a negative blood Wassermann reaction by a positive return from the cerebrospinal fluid is sufficiently common to warrant its consideration.

Increasing importance is being placed upon the fluoroscopic study of the heart and great vessels in luetic aortitis. As pointed out by Kurtz and Eyster,¹¹ the elongation and the widening of the aorta together with the pulsation to the right of the sternum and the visibility of the descending aorta in a subject under 50 years of

FIG. 2. Roentgenogram showing the position of the finger in retrosternal palpation. Contrast for the finger-tip has been afforded by barium sulphate in a rubber coat.

age constitute suggestive criteria for the diagnosis of aortitis. Any construction of such data into etiologic background must obviously be presumptive, but in principle and practice such grounds for the diagnosis of aortitis would appear sound, at least until that stage of life when sclerotic changes make their appearance in the vascular bed. Added to the fluoroscopic examination of the aorta itself should be routine orthodiascopy for cardiac size and contour. Of somewhat less general application and value are teleroentgenograms for cardiac size and oblique or lateral views for the retrocardiac space. If the obvious assistance in the diagnosis of aneurysm in four cases be eliminated from the present discussion, there remain 17 patients upon 11 of whom roentgenologic studies were made. In all of these, adequate data were derived from such observations to warrant a conclusion of aortitis. In one instance (case 8) a negative cardiovascular diagnosis from a clinical standpoint was made positive by roentgenologic study. Unfortunately the other two negative clinical diagnoses (cases 1 and 20) were not checked by roentgenologic examinations.

Syphilis of the central nervous system was associated with syphilitic aortitis in 12 cases. This figure is exaggerated in a clinical sense, for only six of this group showed predominant central nervous manifestations. The remaining six cases so classified were diagnosed in part upon neurologic findings of an objective order or by serologic studies on the cerebrospinal fluid. It must be concluded that for this series, at least, the coincidence of

syphilis of the aorta and of the central nervous system was very high. One patient (case 13) had syphilitic cirrhosis of the liver.

The manner of death constitutes the final point of clinical interest. Circulatory failure accounted for 10 of the group. Of these the termination was sudden in three and slowly progressive in seven. The next most common method of exitus was collapse succeeding malarial therapy. The occurrence of three deaths attributable to this cause should give pause to the use of malarial therapy in central nervous system syphilis complicated by syphilitic aortitis. The other directly determining causes of death were scattered thus: cerebral accident, 2; broncho-pneumonia, 2; rupture of aneurysm, 1; rupture of aorta, 1; ruptured esophageal varix, 1; melanosis, 1.

CONCLUSIONS

Bearing in mind that the group of cases above analyzed represents end-results of syphilitic aortitis in the main, certain conclusions seem justifiable.

1. The diagnosis of syphilitic aortitis in the late stage was relatively accurate by physical methods, abetted by an adequate history.

2. Roentgenologic technique may effect an earlier diagnosis but the etiology cannot be so determined.

3. The Wassermann reaction on blood was positive only in 61 per cent of cases, but further assistance is offered in this direction by the higher incidence of a positive reaction in the cerebrospinal fluid. Hence a check

of all negative bloods by spinal fluid study may be worthy of consideration where doubt exists as to the etiology of an established aortitis

4 Most subjects with syphilitic aortitis succumb from circulatory failure. Failing an early recognition and arrest of the syphilitic process, treatment must later resolve itself into an effort to preserve and support

a failing myocardium in which apparently an intercurrent coronary sclérosis of non-syphilitic origin is the determining factor in inducing degenerative changes

5 Malarial therapy imposes a heavy burden upon the myocardium. Accordingly it should be avoided whenever there is evidence of aortitis with aortic valve involvement

Bronchomoniliasis: A Clinical and Pathological Study with Report of Illustrative Cases*

By OTIS S. WARR, M.D., F.A.C.P., *Memphis, Tennessee*

GENERAL HISTORY

THE history of the higher vegetative organisms began with the work of Hook¹ in the seventeenth century. Saccardo,¹ in 1886, compiled and summarized the information gained up to that time regarding these organisms as pathogenic agents. The revolution in medicine which followed the great discoveries of Pasteur and Koch caused bacteriology to eclipse mycology and only within the last twenty-five years has interest been revived in this important study, due chiefly to Sabouraud, Castellani and Pinoy, and their associates. Castellani has isolated many varieties of monilia and has described the disease entity known as "bronchomoniliasis".

Bronchomoniliasis is a disease of the respiratory organs caused by a fungus of the Genus *Monilia*. From Ceylon, in 1905, Castellani^{1,2} published the first description of this affection and since then cases have been recorded in all climates. From Seattle to Siam, from Baltimore to Buenos Aires come case reports. The only continent

from which reports are lacking is Australasia. In 1915, Boggs and Pincoffs³ reported from Baltimore the first case of pulmonary moniliasis in the United States and since then the disease has been observed from the Great Lakes to the Gulf of Mexico and from the Atlantic to the Pacific, although in the intervening fifteen years only eleven other reports⁴ have appeared in our medical literature.

In tropical and subtropical countries bronchomoniliasis is much more common than in the temperate zone, but, masking under the guise of tuberculosis, it occurs in all climates, no doubt, with much greater frequency than is generally recognized. Realization of the cosmopolitan nature of monilia infection, indistinguishable as it is clinically from tuberculosis, will lead to growing appreciation in all parts of the world of the value of prompt recognition of this pathological entity, for, in its mild form, this disease readily responds to treatment with iodides but, if neglected or treated as pulmonary tuberculosis, it usually ends fatally.

PATHOGENICITY

Since at present the definite biological relationships between the yeast

*From the Polyclinic and the Department of Medicine, University of Tennessee College of Medicine.

fungi are not settled and fixed grouping for the pathogenic forms is as yet undetermined, some eminent mycologists in this country prefer to concur in the custom, practised abroad, of calling all organisms which produce yeast-like forms in abundance and propagate chiefly by budding, 'blastomycetes' and the diseases produced by them 'blastomycoses', using the terms simply in the generic sense. This terminology is confusing and presents a difficulty to the reviewer, for in the United States the blastomycete is generally regarded as a genus as separate and distinct as the Genus *Monilia* or the Genus *Aspergillus*, and in common usage these terms have only a specific meaning.

The Genus *Monilia*, generally regarded as belonging to the 'fungi imperfecti' or hyphomycetes, is widely distributed in the tropical and temperate zones, and is present in the air, especially of the tropics. It lives in nature in the saprophytic state, thriving on decayed wood, dead leaves, and vegetable debris of all kinds. It may attack any organ or system of the body. Castellani's⁶ first investigations were instigated by the constant finding of monilia, in large amounts and without the concomitant presence of tubercle bacilli, in the sputum of persons suffering from a disease entity simulating pulmonary tuberculosis. These persons were employed in tea factories in Ceylon. In the tea leaves and in the tea dust monilia was also found. This initial finding led to studies which have definitely established a large number of species of the Genus *Monilia* as capable of being the sole causative organism in

bronchopulmonary disease. The many varieties are differentiated chiefly by their biological characteristics, especially fermentation of sugars. The types most frequently found in bronchomoniliasis are *Monilia tropicalis* Castellani, *Monilia pinoyi* Castellani, *Monilia metalondimensis* Castellani, and *Monilia krusei* Castellani.

Castellani⁶ found that moniliae with the same biochemical properties may differ enormously in their pathogenicity for man and laboratory animals. Species pathogenic to man may be non-virulent to the usual laboratory animals. The vegetative body or thallus of these organisms appears, in its parasitic stage, as a mass of mycelial threads or free-budding forms in the tissues which it invades. *Monilia* fungi live saprophytically in the human mouth. Parasitically, they attack chiefly the skin and mucous membrane, more rarely the nervous tissue. Bronchopulmonary disease is the most frequent manifestation of monilia invasion. These fungi are not omnipresent but occur in most sputa, and when they appear in large numbers bronchomoniliasis is usually indicated.

Seemingly, the pathogenicity of these organisms in any given case depends largely upon the resistance of the host. In numerous cases a preceding bronchitis, influenza, or pneumonia is mentioned, and in Busse's case, cited by Procházka,⁷ pregnancy and childbirth were apparently primary conditioning factors. Procházka believes that most fungi have only a facultative pathogenicity and that a weakened condition of the host's organism (human or animal) may provide the soil

necessary for the development of full pathogenicity. He suggests that sugar-containing media, such as the sugar beet, may increase the pathogenicity of these fungi. From the consideration that monilia grows best in a medium which contains sugar, Balog and Grossi⁸ believe that it would more readily penetrate a diabetic terrain and they give insulin in consequence. From the analogy with thrush, of which monilia is the most common causative agent, Kotkis, Wachowiak and Fleisher⁹ think it reasonable to interpret bronchopulmonary moniliasis as a condition in which a primary irritating factor, bacterial, toxic or mechanical, initiates changes which permit the fungi to gain foothold, and, once established, to become the essential element in maintaining the irritation.

ETIOLOGIC FACTORS

Most of the cases reported have been in adults, a few suggesting that the infection was contracted in childhood and, after a brief period of activity, lay more or less dormant until middle age. The mode of infection is a matter of conjecture. Undoubtedly, the fungus exists saprophytically in the mouth and may under favorable conditions become pathogenic. Farah¹⁰ and Iacono¹ state that it may be transmitted from man to man. It may be picked up from vegetation, as in the case of the tea factory workers in Ceylon. Balog and Grossi¹¹ believe that the most frequent carriers of the organism in Egypt are dried fruit and straw, and Mautner¹² calls attention to the frequency of the disease among those having close contact with pigeons and other birds, suggesting their food

as a possible source of infection. Since the fungus is prevalent in the air, it no doubt frequently enters the lungs by inhalation. In Ceylon it was found in the nasal cavities of tea-tasters who snuff up tea as well as taste infusions, and Castellani and Chalmers⁵ found that guinea pigs into whose nostrils tea dust was insufflated daily for months developed a broncho-alveolar moniliasis. Haberfield, cited by de Almeida and dos Santos,¹³ thought that the organism entered by inhalation, and later, writing with Lordy, suggested the tonsils as a portal of entry. De Almeida and dos Santos¹³ believe that the organism could travel by the blood stream as well as by the lymph stream.

There are those who agree with Galbreath and Weiss² that at present there is no agreement as to what constitutes the Genus *Monilia* and as to whether it has a primary or a secondary rôle in the etiology of nontuberculous chronic bronchitis. Yet Castellani¹ has grouped the affections due to monilia as follows: (1) Tonsillitis (tonsillo-moniliasis), (2) Bronchitis (broncho-moniliasis), (3) Conjunctivitis (ocular moniliasis), (4) Enteritis (entero-moniliasis), (5) Otitis (oto-moniliasis), (6) Urethritis (urethral moniliasis), (7) Dermatitis (cutaneous and mucous moniliasis). Iacono¹ adds that in certain brain abscesses the cause has been found to be a monilia. Certainly from a nosological standpoint as Farah¹⁰ suggests, every case of bronchitis, especially every one of long standing should be well studied and cultures from the expectoration should be obtained.

SYMPTOMS

Primary broncho-moniliasis appears in three forms, i e, (a) mild, (b) intermediate, and (c) grave. In the mild type the general condition of the patient is good and there is no fever. There is a slight cough with mucopurulent expectoration, often scanty and usually not containing blood. Physical examination of the chest is negative or reveals only a few râles. The intermediate type is characterized by a slight bronchial catarrh and slight fever which is of long duration. The cough, more or less severe, is paroxysmal, occurring morning and night. There may be some degree of dyspnea. In the grave form, the symptoms, the entire clinical picture, and frequently the roentgen picture, closely resemble pulmonary tuberculosis both as to local and general findings. There is the same hectic fever, the gradual and progressive loss of weight, night sweats, and thoracic pain. Cough and dyspnea are severe. There is hemoptysis. The mucopurulent sputum may be of greater or lesser amount. Anemia and emaciation are frequently pronounced. On chest examination, there may be found areas of dullness with increased or diminished tactile fremitus due to consolidation or pleural thickening, bronchial or bronchovesicular breathing, or the breath sounds may be entirely absent, a few inconstant fine crepitations or many moist râles as well as an occasional pleuritic rub.

The course of the disease may be acute, but usually it is prolonged, with remissions and exacerbations, terminating in gradual deterioration or gradual recovery. Some of the intermediate types present the physical

signs of chronic bronchitis rather than of pulmonary tuberculosis. Others present the clinical picture of bronchial asthma. In a number of cases, occurring in different parts of the world, the course has been described as resembling pneumonia. Thus, rigors with high fever are mentioned in a few cases, and in several cases of acute onset the temperature fell by lysis after from eleven to fourteen days, convalescence following. Occasionally, sore throat and huskiness of voice appear as early symptoms. In one or two cases, inflamed tonsils are mentioned. Intense dyspnea is not infrequently noted. Balog and Grossi¹¹ ascribe the dyspnea and cyanosis in some cases to the accompanying myocarditis and decompensation of the right heart, which they attribute to the toxins of the monilia. These authors also mention pains in the lower limbs in cases of long duration.

The cough is paroxysmal, usually worse at night and in the morning. The sputum is sometimes scanty and difficult to raise, sometimes abundant. Except in the mild type of the disease, it is likely to be blood-streaked. It has been described as "like milk", later becoming curdly and pinkish, and again as grey, lumpy and gruel-like with a yeast-like taste. An odor is sometimes present in the breath, variously described as "like yeast" and "like beer fermentation". Castellani¹² remarks that the sputum may have an odor resembling that of commercial yeast. In examining sputum containing *Monilia metalondinensis*, Wheeler and Hoffstadt¹³ detected a yeast-like odor after a short period of incubation.

DIAGNOSIS

The diagnosis cannot be made at the bedside. It is based on (a) finding the fungus—yeast-like cells, more rarely mycelia—in the sputum, and (b) by culture. The species is determined by the specific fermentation of various sugars. The first essential is to obtain the sputum as fresh as possible after the patient has washed his mouth thoroughly with boiled or sterilized water. Castellani¹⁴ emphasizes the importance of having the patient gargle and rinse the mouth with sterile salt solution before being asked to cough or expectorate, because of the frequency with which the monilia fungi exist saprophytically in the mouth. He also stresses the necessity of immediate examination of the specimen in order to avoid air contamination.

Primarily, the diagnosis rests on the absence of tubercle bacilli and the presence of moniliae in the sputum, but cultural investigation and animal inoculation are also necessary. Castellani, Douglas and Thompson⁶ warn that a definite diagnosis of primary bronchomoniliasis should be made with great care and only when the bronchial expectoration, collected with every possible precaution, contains monilia in fair amount, tubercle bacilli being absent, and when the number of organisms decreases rapidly with the gradual improvement of the condition. Tuberculosis is excluded by the skin reaction, repeated absence of acid-fast bacilli in the sputum, and the biological tests. Syphilis and bronchial spirochetosis are excluded by serological tests and by examination for spirochetes. Other fungi are to be considered and looked for in cultures.

Animal inoculation, according to Castellani,¹⁴ provides the conclusive step. His criterion is that intrapulmonary injection into a rabbit must induce the characteristic numerous small white nodules, containing the fungus, in both lungs. It is not sufficient that an injection into the peritoneum or vein produce death in the animal with pneumonia and general septicemia, the strain present in the sputum must be shown to be capable of producing the characteristic lesions in the lungs. In the published cases of bronchopulmonary moniliasis this condition does not appear to have been fulfilled very generally. Some authors do not regard animal inoculation as essential to a final diagnosis.

Balog and Grossi⁸ reported testing eighteen patients who had pulmonary moniliasis, using scarification tests and intracutaneous and subcutaneous inoculations. Using as antigen an emulsion of the fungus killed by heat, they obtained only a general reaction which they interpreted as nonspecific. Thereafter, they employed emulsions made from living, untreated *Monilia pinoyi* Castellani which, they state, is strongly pneumotropic and does not harm the host when inoculated into the skin. With this living antigen intracutaneous inoculations were positive in all eighteen of the patients with pulmonary moniliasis and negative in all of the fifty-three controls consisting of normal healthy individuals or persons suffering from tuberculosis or other disease not due to monilia. The scarification tests were not successful, although intracutaneous tests made simultaneously in the same patients, were positive. In Steinfield's¹⁰ study

of fifteen cases of bronchomycosis associated with certain types of bronchial asthma, intracutaneous reactions could not be interpreted

DIFFERENTIAL DIAGNOSIS

Differentiation from tuberculosis is as difficult as it is important. Mere absence of tubercle bacilli from the sputum is in itself not conclusive. The guinea pig inoculation test for tuberculosis must always be made. Roentgen examination is also important and should never be dispensed with, even though it serves only to rule out pulmonary carcinoma. It appears to be fairly characteristic of the roentgen picture in primary bronchopulmonary moniliasis that the apices remain clear, otherwise, the roentgenogram may correspond to that of tuberculosis in its various stages.

Frequently moniliae and tubercle bacilli are found together in the sputum. In that event, the monilia may be a saprophyte or there may be a true double infection. Balog and Grossi⁸ mention three cases in which they found that the symptoms clearly indicated the presence of the two diseases. They regarded the condition as a genuine moniliasis engrafted on a tuberculous base. Many writers on the subject look upon the fungus as a secondary invader when it is associated with the tubercle bacillus. A large number even assume that it may be disregarded from the therapeutic standpoint. That the fungus, appearing in abundance soon after infection, may antedate the tubercle bacillus in the sputum by months is not deemed significant of its priority as a causative agent. In general once the tu-

bercle bacillus has appeared, it is assumed that it represents the primary infection and bronchopulmonary moniliasis is assigned a secondary rôle.

The opinion, however, that the fungus infection is frequently the primary disease is not without supporters. Some feel that the ensuing pulmonary deterioration provides suitable soil for the subsequent lodgment of the tubercle bacilli. In support of this view Marett's observations are of interest. Ferguson¹⁷ cites Marett as saying that, in the Channel Islands, monilia infection of the lungs is as frequent as tuberculosis, and that most patients with tuberculosis have the double infection. Marett found "blastomycetes" alone in forty per cent of cases of suspected tuberculosis, "blastomycetes" and tubercle bacilli in forty per cent, and tubercle bacilli alone in twenty per cent. His experience led him to conclude that patients of the first class, if left untreated, soon pass into the second, a damaged lung being particularly susceptible to tuberculous infection, and that this second group has an outlook less hopeful than that of the third group who have only the pure tubercle bacillus infection. In order to avoid mixed infection in patients who have tuberculosis only, he urges their isolation from patients who have fungi as well as tubercle bacilli in the sputum. He finds that all cases of true double infection do best by treating the monilia infection first and then proceeding with the tubercle bacillus vaccine. In this, Balog and Grossi⁸ agree with him. Craik,¹⁸ who cites Marett's observations in connection with his own report of a case of bronchopulmonary moniliasis,

says "I think it probable that Colonel Marett has brought to light a truth unsuspected by his predecessors—that chronic blastomycetic bronchial catarrhs occur frequently and that they are the commonest precursors of tuberculosis in this country (England) "

The following is an illustrative case

M. B., aged 56, a merchant, first consulted the author in December, 1923, because of fever, cough, dyspnea, and pain in the chest

Past History Ten years before, he had had an attack of "pneumonia" and was confined to his bed for three months. Thereafter, he had had one or more attacks of "bronchitis" each winter. Tuberculosis was suspected each time, but in no instance were tubercle bacilli found in his sputum.

Present Illness The attack which began late in 1923 kept the patient in bed for a little more than one month. In addition to cough, dyspnea, and a pleuritic type of pain in the left chest, there was an irregular temperature ranging from 99° to 103°. The cough was paroxysmal and there was profuse expectoration of a yellowish mucoid material, occasionally blood-streaked. The respiration was rapid, varying from 30 to 40 per minute. The pulse rate ranged from 110 to 120. Examination of the chest revealed a leathery pleuritic friction sound over the entire left chest. Many moist râles were heard over both lungs, but were most numerous over the lower half of the left. Resonance was impaired, especially over both lower lobes, the impairment being somewhat more marked over the left. Several examinations of the sputum were made. All were negative for tubercle bacilli but *Monilia pulmonalis* was found each time, both on direct smear and in culture. An x-ray examination of the chest (see figure 1) showed extensive infiltration throughout both lungs, more marked on the left with both lower lobes especially involved. Iodide treatment was instituted and at the end of six weeks the patient was able to return to his business. He was, however, still short of breath on slight exertion and continued to have paroxysms of coughing.

Clinical Course He was not seen again for eighteen months. At that time he was having another attack of "bronchitis" similar in every respect to the one just described. The sputum was again negative for tubercle bacilli but *Monilia pulmonalis* was readily demonstrated as before. X-ray examination (see figure 2) now showed a diffuse infiltration of both lungs as before, but with considerably less involvement of the left lower lobe. The amount of lung involvement, on both examinations, was out of all proportion to the patient's symptoms and general appearance. The blood examination showed the following: Hemoglobin, 75 per cent, erythrocytes, 4,400,000, leucocytes, 8,150, polymorphonuclear neutrophils, 76 per cent, lymphocytes, 24 per cent.

Six months later, the patient had another attack which began in every respect like the many previous ones. There was the usual fever, pain in the chest, dyspnea, and cough with rather profuse expectoration. After a few days, areas of consolidation were found in the lower lobes of both lungs. Respiration became very labored and marked cyanosis appeared. The sputum contained considerable blood and was more tenacious than usual. Surprisingly enough, examination of the sputum showed many tubercle bacilli and many pneumococci. No moniliae were found in direct smear but they were grown in culture as before. The patient died at the end of two weeks, apparently from a bronchopneumonia. An autopsy was refused.

In such cases as this it is, of course, impossible to determine definitely which infection preceded. In this particular instance, however, it seems only reasonable to assume that there was a genuine primary moniliasis which provided suitable soil for the later invasion of the tubercle bacilli, the bronchopneumonia serving merely as a terminal event.

Balog and Grossi⁸ emphasize one important point of differentiation be-

tween primary pulmonary moniliasis and the secondary form accompanying tuberculosis. Cases of primary moniliasis of the lungs always show lesions of the base while lesions at the apex of the lungs, or extending to the apex, are identified as mixed forms of tuberculosis and moniliasis, the mycosis being regarded as a secondary infection. A second point of differentiation is that

in secondary moniliasis, the mucous membranes of the mouth, pharynx, and bronchi are usually invaded by the fungus. This is very rare in the primary type of lung infection.

In addition to a symbiotic action between monilia and the tubercle bacillus, other cases of mixed infection of the lungs have been reported. Secondary bronchomoniliasis is not infrequently met with in such cachectic

Fig. 1

FIG. 1. Case 1, M. B. (Dec. 1923). Showing infiltration of both lungs, more extensive on the left and especially marked in the lower lobes.

diseases as cancer and diabetes. *Monilia* finds sugar-containing media particularly desirable soil.

The following case of pulmonary moniliasis occurred in a patient who also had syphilis. The relation between the monilia infection and the syphilis was always problematical.

W. W., male, aged 41, first came to the clinic in December, 1923, complaining of shortness of breath, cough and weakness.

Past History For fifteen years he had been troubled off and on with cough, much wheezing, and dyspnea on exertion. For three years these symptoms had been continuous. Occasionally he had had fever for several days at a time, and a few times the sputum had contained blood. Nevertheless, he had gained twenty-five pounds in weight. For several years he had been having hay fever with attacks of asthma, commencing in August and continuing until frost. Aside from his pulmonary symptoms his general health had been good. There was a fairly definite history of

Fig. 2

FIG 2, Case 1, M. B. (May, 1925) A diffuse infiltration of both lungs still present but a decided clearing of the left lower lobe.

syphilis, but he had considered himself cured

Present Illness At the time of consultation the patient related that the cough, wheezing and dyspnea, which had troubled him continuously for three years, were steadily growing worse and were accompanied by an increasing weakness. He had the appearance of a robust middle-aged man weighing about 200 pounds. His breathing was somewhat labored and examination of the chest revealed a moderate lagging of the left side with greatly impaired resonance over the left base. Many moist and wheezing râles were heard over the

lower half of both lungs, more on the left than the right. The heart sounds were obscured by the wheezing but were apparently normal. The blood pressure was 110/85, the pulse 86, and the respiration 24. The blood count was as follows: Hemoglobin, 90 per cent, leucocytes, 9,150, polymorphonuclear neutrophils, 68 per cent, lymphocytes, 32 per cent. The blood Wassermann was four plus positive. Urinalysis was essentially negative. Several sputum examinations were negative for tubercle bacilli. No cultures were made at this time.

Roentgenological examination of the chest (see figure 3) showed the left lung about

Fig. 3

FIG. 3. Case 2 W. W. (Dec. 1923). The left lung is about fifty per cent collapsed with multiple adhesions between visceral and parietal pleurae resulting in the formation of many pneumothorax pockets. Also an area of consolidation in the right lung shown.

fifty per cent collapsed with multiple adhesions between the visceral and parietal pleurae, resulting in the formation of many pneumothorax pockets. There was no free fluid, but there was an area of consolidation in the right cardiophrenic angle, with some mottling throughout the right upper and middle lobes giving the appearance of pulmonary tuberculosis. The heart and mediastinum were displaced to the left.

Clinical Course Because of the unusual lung findings, the negative sputum, and a strongly positive Wassermann, a tentative diagnosis of syphilis of the lungs was made and an intensive course of antisyphilitic treatment was commenced. Sulpharsphenamine, salicylate of mercury, and iodides were employed alternately. A month later the patient reported that he was much improved, was coughing less, and had less dyspnea. Three months after treatment had begun his general condition was greatly improved but there was no appreciable change in the pulmonary condition either on physical or x-ray examination. The sputum was again negative for tubercle bacilli and the blood Wassermann was still four plus positive.

After two months more of antileptic treatment he was coughing more and expectorating large amounts of yellowish purulent sputum, occasionally blood-streaked. He was having an irregular temperature, at times reaching 102°. He also complained of frequent attacks of a pleuritic type of pain in the right chest. The sputum was now cultured for the first time for possible fungi and *Monilia pulmonalis* was grown in large numbers. During the next twelve months, in addition to the routine antileptic treatment he was given iodides in large doses, both by mouth and intravenously. Under this treatment there was less cough and expectoration, less dyspnea, and a considerable gain in strength. The treatment was continued intermittently and about a year later the roentgenogram (see figure 4) showed that some re-expansion had occurred in the left lower lobe and in the base of the left upper with a diminution in the size of the pockets of pneumothorax. The left lung was still very poorly aerated, showing many areas of increased density, probably fibrosis. No change was apparent in the right

lung. Three months later, examination showed continued improvement but there was one large area of pneumothorax present in the left apex reaching down to the level of the second rib anteriorly. Still no change was seen in the right lung.

In the meantime, several sputum cultures had been made and the monilia was recovered each time. Finally, an autogenous monilia vaccine was given over a period of two months with no apparent benefit. The patient now passed into the hands of another physician who states that for the next three and one-half years the patient's condition was essentially unchanged and that, in spite of the cough and dyspnea, he was able to carry on his work as a traveling salesman. Several sputum examinations were made for tubercle bacilli, all of which were negative. In December, 1929, he developed influenza to which he succumbed in three days.

Mixed infections with two different fungi are occasionally met with. Cases of mixed monilia and anaeromyces infection have been described by Castellani, Douglas and Thompson,⁶ and of monilia and spirochetes by Castellani.¹⁴ They base their belief that each was playing an etiologic rôle on the cure obtained by combining the treatments for the two conditions after treatment for each separately had failed. They suggest that when a mild or moderately severe case of bronchomoniliasis fails to respond to potassium iodide and creosote, mixed infection should be considered and a second organism looked for.

Cases of bronchitis and bronchial asthma, pneumonia, pseudodiphtheria, cancer of the lung, phthisis tuberculosis of the axillary lymph glands, glycosuria, diabetes bronchospirochetosis, anaeromycosis, thrush and dermatitis have all been mentioned in which a more or less important rôle is ascribed to monilia. In its primary

form bronchopulmonary moniliasis should be promptly differentiated, especially from tuberculosis. Even when secondary, it should not be neglected, for it only prolongs the course of the original process and causes further damage.

CLINICAL PATHOLOGY

The moniliae belong to the family of hyphomycetes. There are many varieties. Castellani¹ alone has isolated more than forty species and

others have added to this number. The Genus *Monilia* is characterized by sporophores which are simple or sub-simple and proceed by constriction at their extremities, and by a chain of large lemon-shaped conidia often provided with a disjunctive apparatus. The tendency has been, however, according to Castellani, Douglas and Thompson,⁶ to include under the term "monilia" all the organisms of the family Oosporaceae Saccardo, 1886. The lack of definitely fixed biological re-

Fig. 4

11-1-10-2 W. W. (Mar. 1925). Some re-expansion had occurred in the left lung, with increase in size of the pneumothorax pockets except the one at the apex. No change was apparent on the right.

relationships in the field of the yeast fungi has been mentioned in a foregoing paragraph. When isolated from lesions monilia presents microscopically a vegetable body composed of mycelial filaments of somewhat large size, frequently having arthrospores and numerous free oval or somewhat round "buttons." When grown in cultures, especially on solid media, the organism consists exclusively of oval or somewhat round "buttons." It grows well on solid or liquid media containing glucose or maltose.

In making cultures the greatest care must be exercised to exclude the ordinary saprophytic mouth fungi. Castellani's¹⁴ method is to cleanse the mouth with a wash of a 1:5000 solution of potassium permanganate. The patient then expectorates into a sterile Petri dish. The sputum is inoculated on plain broth, agar and glucose broth. These are incubated at room and incubator temperatures. At the same time, the sputum is examined for protozoa and tubercle bacilli. After forty-eight hours, white colonies, milky in appearance with "cupola" tops, are selected and examined microscopically. The presence of conoid forms about the size of a red blood corpuscle confirms the presence of some species of monilia. Passing the culture through a series of sugars completes the classification of the parasite.

Identification of monilia in direct smears of sputum is by no means easy unless the fungi are present in very large numbers. Pijper¹⁰ finds the resemblance of the oval spores to the nuclei of body cells or even chromocytes very misleading. He mentions a differential stain which he has found

highly satisfactory. In examining the fresh sputum, spirochetes are ruled out by means of dark ground illumination, lung parasites, such as *Paragonimus ingeri* (Cobbold, 1880), by simple microscopical examination, and tubercle bacilli and the acid-fast species of *Nocardia* are distinguished by one of the usual methods of demonstrating acid-fast bacilli. The presence of non-acid-fast species of *Nocardia* and of yeast-like fungi is revealed by coloring films of the fresh sputum by Leishman's and Cram's methods.

The blood findings vary considerably, many investigators finding no important changes in the blood picture while others report marked variations. Some degree of anemia appears to be the rule. A slight leukocytosis has been mentioned a few times, and eosinophilia is frequent.

Complement fixation reactions with the sera of patients have been obtained in some instances, notably in the cases reported by Farah,¹⁰ Kurotchkin and Chu,²⁰ and Hoffstadt and Lingenfelter.²¹ Steinfield¹⁶ found the complement fixation reaction of equivocal value, and concluded that the agglutination reaction gave no new information. Peruchena's²² agglutination experiments with normal and immune sera were negative. In Parise's²³ case the organism was not agglutinated by the patient's serum. Farah,¹⁰ however, found that the fungus gave a positive agglutination reaction with the patient's serum and Hoffstadt and Lingenfelter²¹ noted that this organism showed spontaneous agglutination. A positive precipitin reaction was obtained by Kurotchkin and Chu²⁰ when the patient's serum

was added to various extracts of monilia cells, and control sera were negative. Peruchena's²² attempts to produce hemolysis with cultures failed.

Roentgen examination is of value in all cases. It shows definitely the location of the infection and its progress. A general characteristic of genuine primary bronchopulmonary moniliasis is that the apices remain clear, even in advanced cases. The x-ray also serves to rule out pulmonary carcinoma, and when used in conjunction with lipiodol injections, to exclude bronchiectasis.

Very few postmortem examinations have been reported. A review of the literature on bronchomoniliasis reveals only five authors²⁴ who mention autopsies. The only report of a postmortem examination made in the United States appeared from Baltimore in 1916 when Boggs and Pincoffs³ described the first case of pulmonary moniliasis published in medical literature in this country. The case report appearing at the conclusion of this paper contains a detailed account of the postmortem findings in the author's case of primary bronchopulmonary moniliasis in which *Monilia pulmonalis* was demonstrated repeatedly in the sputum, both on direct smear and on culture. Repeated examinations for tubercle bacilli were always negative.

PATHOLOGY IN EXPERIMENTAL ANIMALS

Castellani²⁴ found that the virulence of different moniliae varies, i. e., (a) a few strains are non-virulent to laboratory animals, (b) certain ones are virulent and will kill a rabbit or a guinea pig following intravenous or in-

trapulmonary inoculation, but without the evident pseudotubercular nodular condition of the lung; (c) others produce a peculiar nodular condition both in the inoculated and in the non-inoculated lung, when injected intrapulmonarily and at times intravenously.

If the monilia isolated from the sputum is nonpathogenic, intrapulmonary inoculation in rabbits produces neither lung lesions nor general infection. When the fungus is virulent but only a secondary invader, intravenous injection will kill the rabbit and intrapulmonary injection will induce a fatal septicemia, but without a localized nodular affection of the lungs. When the monilia is the real cause of a broncho-alveolar condition, intrapulmonary injection will produce in the rabbit a very characteristic nodular condition of the lungs, both lungs becoming studded after two or three weeks with a large number of white nodules which contain the fungus. Some of these nodules may coalesce, forming a staphyloid mass. The smaller nodules are about one-eighth of an inch in diameter and microscopically, contain in their centers masses of small white cells and polymorphonuclear leukocytes which decrease in number peripherally. They are in turn surrounded by a ring of epithelial cells, many containing phagocytized smaller white cells, together with a few large multinucleated giant cells. At times the cells in the center of the nodules are markedly degenerated, the nodules there showing gross caseation. In most instances there is some congestion but no pneumonia between the nodules. Thickening of the intima is present in the small arteries

Castellani¹⁴ maintains that the demonstration of the characteristic nodular condition in the lungs is essential for the establishment of the diagnosis of primary bronchopulmonary moniliasis, while other writers contend that animal inoculation is not even necessary when the sputum is repeatedly positive for monilia.

In their animal experiments, Balog and Grossi⁸ used an emulsion of living mycetes. Intrapulmonary inoculation, as first done by Castellani, they found to be the most efficacious method of injection. They give an excellent description of the lung changes following intrapulmonary inoculation in rats of a strain capable of producing pulmonary disease, and note the remarkable likeness to tuberculosis. Intracardiac inoculation into guinea pigs resulted in death from acute septicemia. Kurotchkin and Chu²⁰ found that intrapulmonary inoculation of *Monilia tropicalis* did not kill the rabbit in from three to five weeks, but invariably produced extensive necrosis in the lung with obliteration of the pleural cavity and formation of a few nodules. Intravenous and intraperitoneal inoculation killed with mycotic septicemia, small disseminated whitish nodules containing the monilia appearing in the lungs and other organs. In general, intravenous inoculation with a virulent strain produces general septicemia, nodules may appear in various organs, with or without simultaneous lung involvement. Intraperitoneal inoculation may or may not succeed.

PROGNOSIS

The mild type of bronchomoniliasis may result in spontaneous cure

and is always readily amenable to specific treatment. Usually the intermediate type also yields to treatment, but the response is slow. A prolonged course of treatment is often necessary. Sometimes this type apparently remains stationary, but, if neglected, it not infrequently passes into the severe form. Except perhaps in its early stages, the severe type is usually incurable, although death may not take place for many months.

Chyruha²⁵ presents from Venice a good example of the chronic intermediate type of the disease. A more severe form which, nevertheless, seems to have changed little over a period of ten years is described in detail by Galbreath and Weiss² from Porto Rico. Colaid and Jauman²⁶ of Belgium describe a case which presents the progressive type. In one of five cases, reported by Stovall and Greeley²⁷ from Wisconsin, the course was rapid, death ensuing in four weeks. This case appears to have been of the severe type from the beginning. The case report which appears at the conclusion of this article illustrates the severe type of the disease.

TREATMENT

The treatment of bronchomoniliasis is based upon the specific germicidal effect of potassium iodide on monilia. This drug has had such beneficial effect particularly in the mild and intermediate cases that it has come to be regarded as the specific. In severe cases however it appears to be of little, if any value. In such cases lipiodol by intratracheal injection deserves extended trial. This may be combined with intramuscular injection

tions Castellani^{6,14} advises that potassium iodide be given in fifteen grain doses in milk or water three times a day, this treatment requiring three or four weeks to effect a cure in mild cases. In addition, he advises creosote, glycerophosphates and balsamics, and tonics to combat the loss of appetite and the anemia. He has found that cases of mixed infection, as for example moniliasis and anaeromycosis, are frequently cured by combining the treatments for the two infections. When possible, the patient who lives in a hot moist part of the world should be removed to a more suitable climate.

Stovall and Greeley²⁷ treated one case with intravenous injections of gentian violet, and saw much improvement. Balog and Grossi⁸ believe that insulin is of value, even in cases without glycosuria. Farah¹⁰ states that pneumosan injections may prove useful. He recommends lipiodol—forty per cent iodine in poppy oil—(2 cc) injected intramuscularly in the gluteal region on alternate days, as this treatment appears to be useful in early stages before there is serious damage to the lungs. Energetic treatment, using "iodides, autovaccine (Stemfeld's method), alkalines by mouth, ultraviolet rays, etc.", produced good results in the chronic case Chyurlia⁵ reported from Venice. In Nasso's²⁸ case of a child who had previously had malaria, despite a negative search for plasmodia, the patient improved under intensive quinine treatment. Craik¹⁸ treated his patient successfully with alkaline potassium iodide and adrenal-
in.

In their case from the Belgian Congo, which had progressed rapidly,

and was in an advanced stage when the patient came under their observation, Colard and Jaumain²⁶ used injections of oil containing iodoform, eucalyptus, and creosote, and intravenous injections of sodium cacodylate and potassium iodide by mouth, all without result. Because of respiratory difficulties artificial pneumothorax had to be discontinued, and because of the venous sclerosis induced, intramuscular injections of Lugol's solution, 6 cc per day, had to be substituted for the intravenous injections. Local applications to the buccopharyngeal lesions were powerless to check their advance. All treatment was unavailing.

Satisfactory results from small doses of roentgen rays in ten cases of bronchomycosis have been reported by Howe and Schmidt,²⁹ but they do not state the kind of fungus involved. Among their patients were two bakers, each having considerable yeast in the sputum. Both were helped by x-ray treatments.

Vaccine treatment has had varying success. Of the forty-three cases Pijper¹⁹ mentions, sixteen were treated with autogenous vaccines only, the doses ranging from fifty million cells to two thousand million cells. Very good results were obtained in three cases and there was distinct improvement in three others, but in the remaining ten cases there was no improvement. This author believes that iodine should be given in addition to the vaccine. Kotks, Wachowiak and Fleischer¹ saw complete disappearance of symptoms following the use of autogenous vaccine in one case, and great improvement in another before it passed out of control. In Stemfeld's¹⁶

fifteen cases, iodides were efficacious and vaccines, prepared from organisms killed by heat, dose 0.1 cc increasing to 1.0 cc, seemed to help. For therapeutic purposes Balog and Grossi¹¹ used the same emulsion of living, untreated *Monilia pinoyi* Castellani as for diagnostic skin tests. By repeated injections with progressively increasing doses, they were able to effect healing in a short time in most cases and to produce great improvement in the remainder. They note that monilia vaccine therapy always acts gently and that desensitization takes place during the treatment. They have found vaccine treatment the only therapy which restores the myocardium after injury by the monilia toxins.

CASE REPORT WITH POSTMORTEM FINDINGS

Mrs. J. H. T., aged 38, the mother of four healthy children, the youngest five years of age, first consulted us in October, 1923, because of fever, cough, and occasional hoarseness.

Family History. The family history was negative.

Past History. The patient had lived in Memphis for the preceding eleven years, prior to that she had lived in Virginia and in Washington, D. C. She had influenza during the epidemic of 1918 and typhoid fever in 1919. In 1920 she had an attack of pleurisy with effusion, apparently with complete recovery. The chest was aspirated at that time but no bacteriological examination of the fluid was made. The following spring (1921) she had a second attack of pleurisy for which she consulted a well known internist in the East who diagnosed pulmonary tuberculosis although sputum examination was negative for tubercle bacilli. Within a few weeks she was free from fever and for the next eighteen months considered herself well.

Present Illness. During the early spring of 1923 she began to complain of cough and hoarseness, and a few times expectorated blood-streaked sputum, but she did not consult a physician. Her weight had remained practically stationary since the attack of typhoid fever four years before, but there had been a noticeable lack of endurance and some shortness of breath on exertion. It was of these symptoms as well as of cough, hemoptysis, hoarseness, and slight fever that she complained when she first consulted us. There were no digestive or urinary symptoms. Her menstruation was normal and regular.

Physical Examination. The patient was a well developed and well nourished middle-aged woman weighing 160 pounds. Her color was normal and she did not look ill. The tonsils were somewhat enlarged and showed evidence of chronic infection. The general physical examination was otherwise essentially negative except for the chest findings.

Chest. Expansion of the left side was diminished. Over the lower part of the left upper lobe and over all of the left lower lobe there was marked dullness and decreased tactile fremitus. Over this area there were moist râles and diminished breath sounds. Both apices were apparently clear but there was an area of dullness without râles in the right axilla. There were no areas of tenderness to pressure.

Heart. The apex beat was neither visible nor palpable. The area of cardiac dullness blended with that of the lung dullness. The heart sounds and rhythm were normal. The blood pressure was 120/80, and the pulse 82.

Clinical Course. In spite of a negative sputum examination we concurred in the previous diagnosis of pulmonary tuberculosis and considered it of the fibroid type. A few weeks later the patient entered a well known tuberculosis sanatorium in North Carolina where she remained for eight months. While there her temperature remained normal except for an occasional slight rise following an injection of tuberculin. Her cough and hoarseness practically disappeared and she gained several pounds in weight. During her stay in the sanatorium repeated sputum examinations were

made for tubercle bacilli all of which were negative. No other bacteriological studies were made. In spite of this clinical improvement x-ray examination showed a definite increase in the area of infiltration in the lungs.

The patient returned to Memphis on July 4, 1924. She looked and felt well. The next day she had a rigor followed by temperature of 103° . In a few hours there developed a pain of pleuritic type in the left

chest posteriorly. The following day she was coughing considerably and the sputum was streaked with bright blood. Examination of her chest showed marked dullness throughout the left lung from the level of the third rib to the base, with diminished breath sounds and tactile fremitus. Moist râles were heard over both lungs but there were more over the left than the right and more over the lower than the upper lobes. Respiration was 36 and the pulse

Fig. 5'

FIG. 5. Case 3 Mrs. J. H. L. (Oct., 1923). Showing a marked homogeneous density involving the lower half of the left lung, with the mediastinum displaced to the left. In the upper portion of the right lung are two areas of similar density, roughly triangular in shape, which seem to be peripherally located and appear to extend toward the center of the lung. Both apices

was 120. For the next ten days she was critically ill, her temperature ranged from 100° to 103°. At the end of two weeks the temperature was normal in the mornings but continued to rise in the afternoons to 101°. The dulness over the left base increased and a possible pleural effusion was suspected. The chest was aspirated but nothing was obtained. The sputum was persistently negative for tubercle bacilli. The total and differential blood count remained normal.

Two months later the general condition of the patient showed very little change. She was still having an afternoon temperature, and the cough and the quantity of expectoration had increased. She had apparently gained in weight but was becoming more dyspneic and had to sleep most of the time on three pillows. She was most comfortable when lying on the left side. Chest examination now showed considerable dulness and more moist râles over the right lower and middle lobes. The right upper lobe and the upper half of the left upper lobe remained apparently clear.

In the meantime, repeated cultural studies of the sputum for fungi had been made and each time there was obtained a pure growth of *Monilia pulmonalis* Castellani. Convinced that we were not dealing with tuberculosis, we commenced the administration of iodides in large doses, at first by mouth and later intravenously. The only noticeable effect of this treatment was a marked increase in the quantity of sputum, in which an occasional streak of blood continued to appear. Sodium cacodylate was then tried, both intramuscularly and intravenously, but to no avail.

Finally, with both lungs apparently solidified except the right upper lobe and the apex of the left upper, the dyspnea was so great that the patient was compelled to sit upright to breathe. There was considerable cyanosis and a moderate amount of subcutaneous edema. The temperature continued to range from 99° to 101°, the pulse and respiration gradually increasing. But, withal, there was no apparent loss of weight and but little anemia. Death occurred on December 24, 1924.

Röntgenological Findings The first x-ray examination, made October 2, 1923 (see figure 5), showed a marked and fairly homogeneous density throughout the left lower lobe which blended with the heart shadow. The mediastinum and the heart were displaced to the left. The upper margins of the density were fringed and invasive in appearance. In the periphery of the right lung there were noted two areas of similar density, both roughly triangular in shape with bases at the periphery and apices toward the center of the lung field, the upper and smaller area seemed to be situated in the lower part of the upper lobe, while the larger area seemed to be in the adjacent part of the lower lobe. The apices of both lungs were strikingly clear.

Five weeks later (see figure 6), the areas in the right lung had increased in size and were becoming more confluent. The density in the left lung had extended upward, especially at the periphery. No new areas were noted. Seven months later (see figure 7), the heart and mediastinum were displaced further to the left, and the upper lobe was so encroached upon, both from the mediastinum and from the invasion below, that only a small portion appeared to be air-bearing. The two coalescing areas in the right side now extended from the periphery to the mediastinum and seemed to involve all of the middle lobe as well as the lower part of the upper lobe. That part of the shadow corresponding to the lower part of the upper lobe showed a lighter central area suggesting cavitation. Several new small areas of density now appeared in the right lower lobe.

The last x-ray examination was made October 2, 1924 (see figure 8), exactly one year from the date of the first observation. The only important changes were found in the right lower lobe, where the areas of density had enlarged and coalesced until the peripheral half of the lobe seemed to be consolidated. Only about one-third of the lungs remained ventilated.

Laboratory Findings When first examined (October, 1923) Blood Hemoglobin, 90 per cent, leucocytes, 7,150, polymorphonuclear neutrophils, 66 per cent,

lymphocytes, 33 per cent, eosinophils, 1 per cent. The blood Wassermann was negative. Urinalysis was negative. Two sputum examinations were negative for tubercle bacilli, no cultures were made.

After return from sanatorium (July, 1924). Blood: Hemoglobin, 90 per cent, erythrocytes, 4,670,000, leucocytes, 10,200, polymorphonuclear neutrophils, 70 per cent, lymphocytes, 27 per cent, eosinophils 3 per cent. Urinalysis was negative. The sputum was repeatedly cultured at this time for fungi and always *Monilia pulmonalis*.

Castellani was obtained in practically pure growth. Oval yeast-like cells with a few club-shaped segments were found every time in direct smears. These were Gram positive. An abundant smooth white growth developed on all the usual media. The same kind of oval cells were found in smears, and as the growth aged and assumed a "fluffy" appearance, bits of mycelium were found. Both continued to be Gram positive. Broth remained clear at first and then a thin pellicle formed. Acid and gas were negative on inulin, dulcitol,

FIG. 4

FIG. 4. Case 3, Mrs. J. H. P. (Nov., 1923). The areas of density in the right and left lungs increased in size and were becoming confluent. The density of the left lung was more extensive than it was before.

and lactose, but at first they were positive on maltose, glucose, and saccharose. There was no gas and very little acid on mannite. As subculturing was continued acid and gas were not produced in any of the sugars. Simultaneous examinations for tubercle bacilli were negative.

An autopsy was performed and cultures were made from the lungs about four hours after the body had been embalmed, but no growth was obtained.

Autopsy Findings Examination was limited to the thorax and abdomen.

Lungs The left lung was reduced to one-third normal size, and adhered closely to the chest wall, held by dense fibrous adhesions of firm consistency and difficult to tear. The visceral pleura in several places was more than 3 cm in thickness and of the consistency of tough connective tissue. The delivered lung presented a ragged appearance, produced by tags of fibrous adhesions.

FIG 7, Case 3, Mrs J H T (June, 1924) The mediastinum is displaced further to the left and only a small portion of the left upper lobe remains clear. The density in the right lung now extended from the periphery to the mediastinum, and some smaller areas had appeared at the right base. Both apices still clear. (For this roentgenogram we are indebted to Dr C P Ambler, Asheville, N C.)

The substance was quite resistant to cutting and its surface presented numerous small cavities rather uniformly distributed. The largest was about 4 cm in diameter, and each connected with a bronchus. These gave the lung a cheese-like appearance. Most of these cavities were smoothly lined and many were filled with a clear jelly-like material. There was but little air-bearing tissue in either lobe. The large blood vessels were moderately thickened. The

lymph-nodes were small, pigmented black, and only one contained lime salts.

The right lung was increased in size, was less firmly adherent to the chest wall than the left, and presented a pale mottled appearance. The visceral pleura was slightly thickened. Only parts of the upper and middle lobes were crepitant. On the cut surface a few cavities were found. These resembled closely those found in the left lung as to size, lining and contents, while

Fig. 8

Fig. 8. Case of Mrs. J. H. I. (Oct. 1921). The areas of density in the right lower lobe are of solid and are composed of lymphatic tissue. The peripheral half of the lobe. Not much change

the remainder of the lung substance was consolidated as in pneumonia but differed in gross appearance. The consolidated portion was easily torn. The torn margins resembled frogs' eggs in shape and consistency. The entire cut surface presented a glistening, shiny, grayish, translucent appearance not unlike that of a colloid carcinoma. The entire right lung, except a portion of the middle lobe and the apex of the upper lobe, was consolidated. It was estimated that less than fifteen per cent of the lung was air-bearing.

Heart The pericardial sac was drawn to the left by neighboring adhesions. The heart and vessels were otherwise normal in every respect. The aorta presented a few linear patchy areas of intimal thickening.

Liver The liver was slightly enlarged and the cut surface had the appearance of passive congestion.

Spleen The spleen was about normal in size and consistency. The cut surface presented several small firm tubercle-like bodies.

Other Organs The other abdominal and pelvic organs were essentially normal.

Microscopical Findings were as follows.

Lungs The bronchial epithelium was usually denuded—that which remained showed metaplasia. The bronchial walls were necrotic and infiltrated with mononuclear wandering cells and lymphocytes with an occasional red cell and polymorphonuclear leucocyte. This infiltration extended from the bronchial walls to the immediately surrounding alveoli. The remaining alveoli were characterized by the following changes: (1) The filling and dilatation of the entire alveolus with serum albumin. (2) The presence of a fibrin-like material occupying the alveolus with the exception of an area subjacent to the alveolar epithelium. Embedded in this fibrin-like material were peculiar large pale cells of different sizes and shapes, with unusually well defined cell membranes. There were definite connections between the fibrin-like material and the cell membranes. These cells were usually round, at times oval, but in the very large empty forms, pseudopodia-like structures occurred. The cytoplasm stained very

pale, was reticular, granular or stippled, but occasionally crescentic-shaped forms occurred, formed by large clear empty spaces which crowded the nucleus and the cytoplasm to one end of the cell. The nuclei were leptochromatic but large and occupied about one-half of the cell space. Some cells contained two small nuclei. An occasional cell was found with pyknotic nucleus but without cytoplasm. (3) The occurrence of syncytial masses in the same alveolus with the fibrin-like material described above, but distinct and separate therefrom, usually lying at one end of the alveolus and but rarely in its center. They stained dark red and were large, round, kidney shaped or crescentic. In the smaller masses the nuclear structure was distinct and well defined while in the larger ones the nuclei were less well preserved and very poor in chromatin. The nuclei occurred in the center or the periphery of a mass.

The alveolar walls, especially about the larger bronchial vessels, were infiltrated with the same types of cells. Their vessels were engorged with red blood cells, but necrosis and rupture of their walls were also present. In some areas, compression atelectasis was prominent. The large pale cells previously described were to be found lining some of the alveoli, at times in aggregate nuclear masses. The lung tissue, subjacent to the pleura, was characterized by fibrosis, with an occasional small area of necrosis or infiltration with mononuclear wandering cells.

Lymph Glands The lymph glands showed diminution in size of the cortical germinal centers and widening of the pulp medullary spaces with increase of the latter's contents.

We are indebted to Miss Florence M. Frost, formerly Director of Laboratories of the Polyclinic, for the careful cultural studies and for their description in this case. For performing the autopsy and for the description of the findings we are indebted to Dr. J. A. McIntosh, who was at the time Associate Professor of Pathology in the College of Medicine of the University of Tennessee. We desire also to express our appreciation to Dr. I. D. Michelson, emi-

nent mycologist and Professor of Bacteriology in the College of Medicine of the University of Tennessee, for the description of the microscopical findings, and for his invaluable assistance and helpful criticism in the preparation of this paper

DISCUSSION

In Case 1 the monilia infection apparently antedated the invasion of the tubercle bacilli. In Case 2 it is doubtful whether any direct relation existed between the moniliasis and the syphilis. Case 3 was apparently complicated by no concomitant factor, even though treated for many months as tuberculosis and preceded by influenza and pleurisy. It illustrates many of the salient features to be considered in dealing with fungus infection, emphasizing the importance of early recognition, of prompt differentiation, particularly from tuberculosis, and of repeated bacteriological and roentgen examinations. A unique feature in this case was the very sudden onset of the acute stage which continued unabated to a fatal termination in a relatively short time. In two cases of rather advanced tuberculosis, not mentioned in this series, we were able to demonstrate *Monilia pulmonalis* in the sputum and in these cases we believe the yeast-like organisms were essentially secondary invaders.

It seems reasonable to assume that the monilia is a secondary invader although it may be the chief factor in maintaining the chronicity of symptoms in some types of pulmonary disease. As Procházka, Kotkis, Wachowicz and Forstner¹ and other writers have suggested it is quite possible that

some irritant agent, bacterial, toxic or mechanical, may initiate in the mucosa of the bronchus certain changes which make it possible for the monilia not only to maintain its existence but to grow. If these assumptions are correct, we may have to interpret bronchomoniliasis and probably many other types of bronchomycosis as conditions in which a primary factor, either still active or no longer acting, has initiated certain changes which have permitted the fungi to gain foothold and to find more or less permanent lodgment in the bronchi. The numerous cases, such as Case 3, in which a preceding bronchitis, influenza, pleurisy or pneumonia is mentioned, suggest a lowered resistance of the host, thus providing a suitable soil for the development of these fungi. We must concede that, once established, they are capable of becoming and not infrequently do become the essential and important element in maintaining the irritation in the lesions which they invade. In studying such cases we should as a rule look beyond the relatively avirulent moniliae, without in any way ignoring the rôle of these fungi for some other possible factor in the causation of the chronic inflammation. Also, we should certainly study very carefully all cases of chronic bronchitis, tuberculosis of the lungs and other pulmonary diseases of long duration especially those which in any way run a peculiar clinical course, and in such cases should insist upon repeated bacteriological examinations for fungi.

Post-Vaccination Encephalitis*

By CHARLES ARMSTRONG *Surgeon, U S Public Health Service,
Washington, D C*

POST-VACCINATION encephalitis is a disease of unknown etiology that has appeared in recent years and which occurs without regard to the existence of known factors other than the presence of a recent vaccination against smallpox. The disease has a mortality rate of approximately 43 per cent and has associated with it pathological changes of the central nervous system which are similar to those found in the acute nervous manifestations occasionally noted following smallpox, chicken pox, measles and certain other acute infections.

HISTORY AND EPIDEMIOLOGY

Lucksch⁴ in June, 1924, published a series of three cases with post-vaccination nervous manifestations which occurred in Czechoslovakia. Following this publication, some 600 such cases have been reported from Europe—Holland, England, Germany and Norway, in the order named, having suffered the greatest number of cases. A number of additional European countries have had a few cases. Outside of Europe reported cases appear to be mainly confined to the United States.

An isolated case or two has been reported from both Asia and Africa while Australia, South America, Central America, Mexico and Canada have not reported instances of this complication, notwithstanding the fact that, during the last few years, authorities in these countries have been on the alert for them. In the United States 51 proven or probable cases have been recorded for the ten year period just prior to 1931. Forty-one of these occurred during the last three years of this period, or a rough estimate of one case for each 350,000 vaccine points sold in the United States during 1928, 1929, and 1930.

Not only has post-vaccination encephalitis when judged on the basis of reported cases, shown a tendency toward unequal international distribution but within the various heavily involved countries it has shown a tendency to greater prevalence in certain localities than in others. This peculiar localization of cases seems scarcely to be explained by the relative number of vaccinations performed in the different localities or by differences in the methods of vaccination which were employed. Nor have the cases followed the employment of any particular vaccine virus. A striking number of instances have also been reported in

*Presented at the Baltimore Meeting of the American College of Physicians March 24, 1931

which two cases have developed in the same family

The heaviest incidence encountered in the United States occurred in a city of approximately 450,000 inhabitants, where among some 5,000 primary school vaccinations there were five cases, vaccinated within a period of thirteen days, which developed post-vaccination encephalitis. These cases were vaccinated by five different vaccinators who employed various types of single insertions. The same manufacturer's vaccine was used in each of the five cases. This fact, however, loses significance since this producer sold most of the vaccine virus used in the locality referred to during the fall of 1930. The same producer, moreover distributed vaccine virus to many localities of the United States without similar group incidence having been noted elsewhere. Moreover, cases are known to have followed the use elsewhere of vaccine prepared by several different manufacturers. In the affected areas of Europe cases have followed the use of rabbit brain virus, as well as calf strains from many sources including virus imported ready to use from countries in which post-vaccination encephalitis had not been reported.

The complication occurs usually but not invariably following the first or primary "take" and is, therefore, largely confined to children. Adults are, however, occasionally attacked. In affected countries where infant vaccination is practiced to a considerable extent a relative rarity of this complication has been noted following vaccinations performed during the

first year of life, the incidence being estimated by Scott⁵ as about one-sixth of that observed following primary vaccinations performed at later ages. However, if the comparison were made between primary vaccinations under one year and those performed at school age the figure would be probably even more favorable to infant vaccination. In the United States the cases so far reported range from 3 to 49 years in age. Both males and females are susceptible. The complication may develop from a few days to several weeks following the vaccination but there is a striking tendency for it to make its appearance from the tenth to thirteenth day inclusive following primary vaccinations, with a tendency for the interval to be somewhat shortened in cases which follow secondary vaccinations. In other words post-vaccination encephalitis when it develops usually appears when the vaccination is at its height.

European cases have usually followed multiple insertion vaccinations, this, until recently, being the approved method of vaccination in the affected countries. In some instances the complication has followed local "takes" of exceptional severity and in at least one instance was accompanied by a synchronously appearing generalized eruption interpreted as generalized vaccinia.

European cases have, however, appeared following single insertion vaccinations and in the United States all the cases have followed this type of insertion. The evidence, moreover, is clear that in many instances the local "takes" ran a satisfactory course and

were not of exceptional severity

CLINICAL PICTURE

The onset in post-vaccination encephalitis is usually sudden with a feeling of illness, fever, vomiting and headache. Drowsiness and coma may supervene rapidly.

The neurological symptoms vary markedly in individual cases and may point to a major involvement of the meninges, the brain, the brain stem or the cord. Depending upon the regions involved several types of the disease have been recognized by those who have studied particularly the clinical manifestations.

1 *Meningeal Type* This type is common in infant cases, is marked by vomiting, headache, rigidity and retraction of the neck and often by convulsions. The Kernig and Brudzinski signs may be positive and a meningiticcy may be present.

2 *The Cortical Type* In this type convulsions are the most prominent symptom. In two cases of our series convulsions appeared suddenly after the children who were considered to be quite well had been put to bed for the night. Both tonic and clonic convulsions may occur in the same individual accompanied by loss of consciousness. Disturbances of sight and hearing may be present. Such attacks may be rapidly fatal, death in one of the cases investigated resulted within twenty-four hours from the onset of symptoms which made their appearance eight days following the vaccination. In one non-fatal case of this type there is marked mental deterioration with attacks of petit mal apparent after a period of two years. In another case attacks of petit mal are

still appearing six months after the subsidence of acute symptoms.

3 *Brain Stem Type* In this type somnolence, rigidity, tremors, twitching, with altered reflexes, are usual features. The eye muscles usually escape but may show involvement in some cases.

4 *The Myelitic Form* Here the involvement of the lower motor tracts may produce a picture simulating that of poliomyelitis with crippling of one or more extremities. However cases showing a complete paralysis of the lower limbs, such as would almost surely give a bad prognosis for prompt recovery of function in poliomyelitis, may clear up dramatically within a few days. In other instances the myelitic form may present the picture of a transverse myelitis with loss of motion and sensation below the involved segments. In one case of this type which we have observed there is still complete loss of motion and of sensation below the affected segment after a period of six months. Cases of this type have, however, been reported in which recovery has taken place more or less promptly.

5 *Tetanic Form* A tetanic type with trismus and opisthotonus as prominent symptoms has been occasionally noted both in this country and in Europe. Such cases are of especial interest in that they may be confused with post-vaccination tetanus. The clinical picture in these cases, however, has as a rule been rather atypical for tetanus.

While these five clinical types of post-vaccination encephalitis have been recognized among pathologically confirmed cases and are of assistance in

the clinical understanding of the disease, it should be remembered that the classification is an arbitrary one and that most cases present symptoms suggesting two or more of these clinical groups. For instance, headache, drowsiness or coma, rigidity of the neck, convulsions—often of Jacksonian type, incontinence or retention of urine, altered reflexes and paresis or paralysis are features which may be met in cases which differ markedly in other respects. Sensory disturbances have been most frequently noted in the lower extremities. Loss of hearing and sight have been noted in a few instances. It is to be noted that alertness is sometimes encountered in place of the usual lethargy and pains may be prominent symptoms. Trophic disturbances have been occasionally met with.

DIFFERENTIAL DIAGNOSIS

Cases have been mistaken for meningitis of epidemic or tuberculous type, meningismus, encephalitis lethargica, poliomyelitis, sunstroke, cerebral hemorrhage, tetanus, epilepsy, and hysteria. In central nervous disorders the patient should always be examined for the presence of a recent vaccination "take." The presence of a vaccination performed within 30 days of the onset of nervous symptoms should suggest the possibility of post-vaccination encephalitis. In case the onset falls between the tenth and thirteenth days inclusive, this fact is of equal, if not indeed of greater importance, in making a diagnosis of post-vaccination encephalitis than is the character of the nervous symptoms. Furthermore, when the differential diagnosis lies between post-vaccine

tion encephalitis and post-vaccination tetanus an interval of 14 days or less from vaccination to onset of symptoms strongly favors post-vaccination encephalitis, while one of 17 to 24 days or longer strongly favors post-vaccination tetanus. The spinal fluid in post-vaccination encephalitis is clear, shows no visible or cultivatable organisms, and may be essentially normal. However, it is usually under increased pressure with an augmented cell count. In a few instances vaccine virus has been demonstrated in the cerebro-spinal fluid but this has been an exceptional finding.

PATHOLOGY

The central nervous system changes encountered in post-vaccination encephalitis are distinct from those of poliomyelitis or of encephalitis lethargica, but are similar to those encountered in the nervous system involvement which occasionally follows acute infections other than vaccinia. The characteristic finding in these cases consists of adventitial and periadventitial round cell infiltration mainly confined to, but distributed throughout the white matter of the brain and cord. With the Weigert or other appropriate staining method zones of myelin degeneration may be seen centered about the smaller vessels and gradually fading into normal myelin tissue. These perivascular lesions usually, though not always, have shown a symmetrical distribution. Their number and intensity may, however, vary at different levels, a fact which accounts for the variability of symptoms.

PROGNOSIS

Among the cases so far reported 13 from each hundred have ended

fatally In non-fatal cases the recovery is usually prompt and without sequelae Exceptions to this rule are, however, far from rare

PREVENTION

Beyond the fact that vaccinations performed during the first year of life are relatively less liable to be followed by post-vaccination encephalitis than are primary vaccinations performed later, little is known as to prevention

The Rolleston Commission in Great Britain recommends the abandonment of multiple insertions in favor of a single small implantation of virus and is experimenting with dilutions of lymph While such measures aimed toward a milder type of local and general vaccination response would seem to be indicated, their value in the prevention of the complication under discussion has yet to be established

TREATMENT

In addition to symptomatic treatment great care should be taken to pre-

vent the development of bed sores, or of cystitis in cases requiring catheterization Horder,³ Hekman,² and Gruneberg¹ have utilized the serum from vaccinated individuals, preferably those recently vaccinated, in the treatment of fourteen cases of post-vaccinal encephalitis and consider their results as encouraging The same treatment has been employed in a few cases in this country but without any clear indication as to its value

ETIOLOGY

While a definite relationship between vaccinia and the occurrence of post-vaccination encephalitis has been established, the exact nature of this connection is still obscure Attempts to produce the condition in laboratory animals have in the opinion of most workers met with uniform failure Various hypotheses have been advanced in an effort to explain the occurrence of the condition but time will not permit of their consideration

Clinical Aspects of Portal Cirrhosis*†

By ALBERT M. SNELL, M.D., F.A.C.P., Rochester, Minnesota

STUDIES on the experimental pathology of the liver have thrown light on many obscure clinical features of portal cirrhosis, and have shown the significance of certain points concerning the genesis and course of the disease which are not generally appreciated. The fact that ascites can be produced only occasionally in animals, and then only with difficulty, and after much injury has been done to the liver, suggests that in man the clinical syndrome of portal cirrhosis with ascites must represent the terminal stage of a long-lasting disease. Just as the general well-being of animals which are receiving daily sublethal doses of hepatic poisons persists until the amount of functioning hepatic tissue is reduced to a critical point, so does the human victim of cirrhosis frequently remain unaware of the presence of the disease until irreparable injury has been done.

The hepatic lesions which are included under the generic term of hepatic cirrhosis are supposed to represent the end-result of a process of repair and progressive fibrosis consequent on successive focal degeneration

or necrosis of the hepatic cells at the periphery of the lobules.⁴² The reparative processes eventually restrict the portal, venous and capillary bed, and the anatomic end-result is disorganization of hepatic structure with lobulation and formation of adenomas. The physiologic end-results are two: portal hypertension and hepatic insufficiency.

Theoretically any toxic substance which is capable of destroying or injuring hepatic cells, and which may act intermittently over a long period of time, is capable of producing the anatomic lesions of cirrhosis. Whereas a number of factors probably enter into the production of the disease, the end-result is apparently not specific for any particular agent. So far as can be seen now, it appears that the various forms of cirrhosis resulting from diffuse infectious processes such as syphilis, the use of alcohol, or of several other chemical poisons, are much alike clinically and even pathologically. It is for this reason that a clinical classification of cirrhosis is so hard to make. Many clinical types have been described, some of which are reasonably well defined. Among these may be mentioned: (1) portal cirrhosis with either hypertrophy or atrophy of the liver, (2) biliary cirrhosis, either primary or secondary to extrahepatic biliary obstruction, (3)

*Read before the American College of Physicians, Baltimore, Maryland, March 25, 1934.

†The author desires to acknowledge the assistance of Dr. J. H. P. in the preparation of this manuscript.

pigmentary cirrhosis (hemochromatosis), (4) capsular cirrhosis (polyserositis), and (5) the cirrhosis of Wilson's disease. For the purposes of this paper portal cirrhosis may be defined as the end-stage of a degenerative or inflammatory hepatic lesion which has reached the stage of lobulation and which more or less restricts the portal venous circulation.

ETIOLOGY

Experimental cirrhosis has been produced chiefly by toxic substances which enter the liver through the portal blood stream. Biliary cirrhosis secondary to experimental obstruction of the common bile duct may progress to portal obstruction and ascites. Clinically, a similar situation prevails. There are many etiologic agents which are supposed to be capable of causing hepatic injury, but the evidence against most of them is largely circumstantial. Alcohol may be cited as a case in point. Although about fifty per cent of patients with portal cirrhosis admit the use of alcohol, not all of them have been heavy drinkers, and in only about five per cent of patients who exhibit marked evidence of alcoholism do hepatic lesions of any great consequence develop. There is, however, as Rowntree⁴⁴ and others⁴⁵ have shown, some parallelism between the death rate from alcohol and that from hepatic cirrhosis. Functional hepatic injury after abuse of alcohol has been demonstrated by von Bergmann,⁴ by means of tests on the rate of excretion of bilirubin, he has shown, also, that a similar delay in excretion of bilirubin exists in chronic alcoholism and in portal cirrhosis.

Although alcohol will not produce entirely satisfactory experimental cirrhosis, hepatic necrosis and fibrosis may follow its prolonged administration.¹⁵ It seems well established that it is capable of producing structural hepatic injury, but whether it acts directly or through some intermediary product is unknown. It is known to produce changes in the gastro-intestinal tract which may in themselves be the source of toxic substances, or it may permit absorption of the latter from the intestine. It is also recognized that alcohol may act as a solvent for toxic organic substances of intestinal origin. Obviously not all cirrhosis is of alcoholic origin. In India, alcoholism is rare but cirrhosis is common.⁴³ Yang,⁵² in reporting eighty-four cases of cirrhosis in Chinese, found that alcohol could be a factor in only two cases.

The relation between cirrhosis and syphilis is also debatable. The typical result of syphilitic inflammation in the liver is the so-called *hepar lobatum*, but diffuse syphilitic hepatitis may produce a cirrhotic process indistinguishable from the alcoholic type.²⁷ LeDuc²⁷ claimed that seventy-five per cent of patients with cirrhosis have microscopic evidence of syphilis elsewhere in the body. Experience at The Mayo Clinic has shown that one-fourth of the patients in the ascitic stage of cirrhosis have had either a positive Wassermann reaction or a more or less definite history of syphilis. Of nine of the patients who came to necropsy with cirrhosis and serologic evidence of syphilis, only one had typical *hepar lobatum*, the remainder presented the usual picture of

atrophic cirrhosis I have therefore included in this study cases of portal cirrhosis in which syphilis may have been a cause, but in which the symptoms did not disappear under specific treatment

In my experience, cholecystitis and infection of the biliary tract are frequently associated with cirrhosis, but the evidence is not sufficiently complete to differentiate cause and effect. Koster²⁶ and his associates have described early fibrotic changes in the periportal tissues of patients with chronic cholecystitis, and expressed the belief that these changes were secondary to cholelithic disease, and that the spread of infection was by way of lymphatic channels. Other types of gastro-intestinal disease may enter into the genesis of cirrhosis. As Opie³⁰ has suggested, a combination of bacterial infection and chemical intoxication may be involved. The liver may also be injured more or less severely by many of the infectious diseases. In Yang's³² series, fifty patients gave histories of bacillary dysentery or typhoid fever, a previous history of typhoid fever is not uncommon in cases of cirrhosis studied at The Mayo Clinic. Other possible etiologic factors are inorganic arsenical poisoning,³³ hyperthyroidism, toxemia of pregnancy, chronic intoxication³⁴ from protein and malaria.

Certain observations on the experimental aspects of cirrhosis must be considered in a study of the etiology of the condition in man. Research workers agree that when they stop giving the drug which is destructive to the liver the liver of the animal returns to its approximately normal state pro-

vided the lesion is not too far advanced. From this one must infer that in man the poisons which produce cirrhosis must operate continuously over a long period of time. Experimentally there is also marked individual variation in the response of the liver to chemical injury. As Bollman and Mann⁸ have suggested, the response may be due to the state of the liver at the time the toxic agent acts, or it may bear some relationship to the hepatic reserve of glycogen present in the organ at the time.

An obscure point in the pathogenesis of cirrhosis is the nature of the overgrowth of connective tissue which follows some forms of hepatic injury, and which is absent in others. The stimulus to formation of connective tissue apparently must be an essential element in the etiology of portal cirrhosis. It is also recognized that previous hepatic injury leaves the liver with a variable amount of regenerated hepatic tissue, which has been shown to be unusually susceptible to injury. In other words, successive degenerative lesions of the hepatic parenchyma are more and more easily produced, and each in turn interferes further with the hepatic blood supply. The ability of experimentally produced anoxemia^{31, 35} to cause degenerative changes in the hepatic cells must also be considered. Recent studies by Rich³¹ show that anoxemia may operate as a cause of depressed hepatic function, from these studies it is apparent that the hepatic arterial blood flow may be of great importance in determining the course and progression of any hepatic lesion.

CLINICAL STAGES OF CIRRHOSIS

It is clearly established that, in both animals and man, portal cirrhosis may be present without ascites or, in fact, without any marked symptoms of visceral disease. This may be attributed to the enormous physiologic reserve of the liver, to its remarkable regenerative properties, and to the collateral circulation which accompanies the sclerosing types of hepatic lesions. The course of cirrhosis may therefore be divided into two stages, one a preascitic stage, and the other an ascitic stage, or, as Rowntree⁹ has stated, an hepatic lesion may exist either with a compensated or a decompensated portal circulation. The relative frequency of the two stages of the disease is not definitely known, but it has been said that ascites develops in from fifty to eighty-five per cent of cases of cirrhosis. The compensated, or preascitic, stage of the disease has attracted little attention, the attention of physicians has remained focused on the end-stage of the disease. More complete knowledge of the nature and duration of the preascitic stage is now highly desirable. I have, therefore, attempted to review the cases of portal cirrhosis seen at The Mayo Clinic from 1924 to 1929 inclusive with the idea of learning something about the clinical course, the symptoms of the earlier stages, the criteria on which a prognosis can be based, and the rationale of medical and surgical treatment.

The material to be studied comprises 399 cases divided into three groups. (1) 135 cases in which nodular cirrhosis of the liver was discovered in the course of surgical operations for other abdominal lesions,

(2) 152 cases in which a clinical diagnosis of portal cirrhosis in the preascitic stage was made, and (3) 112 cases of cirrhosis in the terminal or ascitic stage. Some idea of the incidence of cirrhosis among patients in the clinic may be gained from the fact that, in the period of six years covered by this study, 399 patients were found to have the disease in a total of approximately 400,000.

Cirrhosis Discovered at Operation

In the group of 135 cases, in which the disease was discovered at operation, hepatic lesions were suspected in only a few, and then because the spleen had been found to be enlarged. I have excluded from this group patients with obstructive lesions of the common bile duct, and those whose hepatic lesions were more localized than diffuse. In some of this group biopsy of the liver was obtained, but in most instances the diagnosis was made from the gross appearance of the liver only. It is probable that some cases were overlooked, since the liver may appear grossly normal and yet contain the microscopic lesions of portal cirrhosis. It is also probable that there were some positive errors of diagnosis, but in general the surgeon's opinion may be regarded as reliable.

The observations at operations in which cirrhosis was found accidentally are given in figure 1. The number of cirrhotic livers discovered at operation on the gallbladder is not large considering that approximately 7000 operations were done on the biliary tract in this period. The discovery of cirrhosis at this type of operation may perhaps be explained on the basis of the proximity of the liver and the

extrahepatic biliary tracts. However, many experienced surgeons feel that lesions of the gallbladder, of long standing may lead to a cirrhotic process in the liver, at least it is agreed that the two conditions are not infrequently associated. This view, which rests on clinical impressions only is partially substantiated by the views of Koster²⁶ and his collaborators. There is, of course, a possibility that the disease of the liver may have been primary, and that of the gallbladder, secondary.

That cirrhosis was found in the course of approximately twenty operations which were done for peptic ulcer was somewhat surprising. It may be that these ulcers were secondary to the hepatic lesion present, since Bollman⁷ has found that in experimental obstructive jaundice, typical callous ulcers of the duodenum are commonly found. Beig and Jobling³

have also advanced the view that hepatic lesions may favor the formation of peptic ulcers.

The cirrhosis which accompanies Banti's disease needs no further comment. Johnston's²³ recent paper contains a summary of the current views on the subject. Thirteen of the patients with Banti's splenomegaly had cirrhosis of marked degree, with reduction of about fifty per cent in the size of the liver. Hepatic functional tests were made in a number of these cases and only moderate retention encountered. Excluding the group with Banti's disease, only eight of the 135 patients had definite splenic enlargement, and in only a few was there any mention of the collateral circulation. From this fact it would appear that in primary portal cirrhosis an enlarged spleen occurs late, when the portal circulation is greatly restricted and that interference with flow of

FIGURE 1. Comparison of the frequency of various conditions in patients with cirrhosis of the liver.

portal blood must exist for some time before collateral channels are established

The symptoms which brought these patients to operation are of some interest. Thirty had typical gallbladder colic, twenty-eight had pain in the upper part of the abdomen, and soreness associated with some indigestion, eighteen complained of poorly localized or bizarre abdominal pain, seventeen had the typical syndrome of peptic ulcer, and ten of these seventeen gave histories of hematemesis and melena. Gastro-intestinal bleeding, without other symptoms, was noted in nine cases. Nine patients gave histories of jaundice. In reviewing these histories, it is difficult to see how hepatic disease could have been suspected in more than a small percentage of the cases. The routine inquiries as to alcoholism and syphilis gave little, if any, information of value since only nine of the patients admitted the abuse of alcohol and only six gave histories of syphilis.

The outcome of the disease in this group of cases is of considerable interest. Nine patients subsequently had ascites, twenty-four have died, and in at least fourteen the hepatic lesion found at operation apparently was responsible for death. The immediate surgical mortality in the 135 cases was not high, so that the subsequent death of the patients may perhaps be attributed to the progress of the disease in the liver. Of the patients with Banti's disease only two have died and the death of one could not be attributed to hepatic disease.

Many of the surviving patients have written to complain of indefinite gaseous dyspepsia, weakness or gas-

tro-intestinal bleeding. On the other hand, a large group have replied to letters of inquiry with the statement that they were perfectly well. The subsequent health of a number of the patients with livers described by the surgeon as being markedly atrophic or "hobnail" in appearance, has remained good and they have experienced no inconvenience. In many of these cases it is hard to see how the operation could have had any effect on the course of the cirrhotic process, but in some the formation of postoperative adhesions may have helped to establish collateral circulation, which in turn may have deferred the development of ascites. In some the removal of diseased gallbladders may have had beneficial effect.

Preascitic Portal Cirrhosis Diagnosed Clinically. In the group of 152 cases in which a clinical diagnosis of portal cirrhosis was made in the preascitic stage, confirmation was not obtained by operation or necropsy. A large percentage of these diagnoses were made because a history of alcoholism or syphilis was associated with the finding of a large liver or spleen and definite retention of dye. The accuracy of diagnosis may of course be questioned, and no doubt some of the patients were suffering from carcinoma or other serious visceral disease. Diagnostic accuracy in the early stages of cirrhosis is disappointingly low and positive criteria have not as yet been established. Often the few symptoms that present themselves are not pathognomonic and the diagnosis must frequently rest on objective evidence.

In the series of 152 cases the most common complaints were of vague abdominal pain, gaseous indigestion, weakness and intermittent jaundice, which was usually painless or almost painless. An enlarged, firm liver was noted in the majority of the cases, and a palpable spleen was commonly found. Edema and signs of collateral circulation were uncommon. In this stage of the disease there was usually only moderate retention (graded 1 or 2) of phenoltetrachlorophthalein or bromsulphalein. More delicate functional tests^{1,19} might have revealed more striking changes.

Seventy-two of the 152 patients are known to be dead, fifty-eight cannot be traced, and only fourteen are known definitely to be living after periods of observation averaging about four years in length. A follow-up study of this group is now being carried out, so that the details presented here are necessarily incomplete. Ascites is known to have developed in nine of the cases.

A few other patients who had a small amount of fluid at the time of examination appear to have recovered completely. One patient in whose case the diagnosis of syphilitic hepatitis was considered, but not proved, regained health under the use of iodides. Another patient with a large liver and marked retention of dye was reported as being well a year after examination. Two patients appear to have died suddenly from gastro-intestinal hemorrhage, and several have died in coma. The high mortality in the group gives striking evidence of the gravity of the condition even in the early stage of cirrhosis.

On the basis of experimental evidence, it seems probable that in the earlier stages of cirrhosis the liver should be able to regenerate, and to become fairly normal, provided the cause of the disease could be recognized and removed. That this actually happens at times is shown by the cases, which are not infrequently reported, in which a man who has been a heavy drinker, and who has begun to show signs of cirrhosis, stops drinking, gets well, and stays well. When etiologic agents continue to act, however, as they apparently do in a majority of cases, the pathologic process continues unchecked, and a fatal termination is the rule.

Cirrhosis with Ascites The appearance of free fluid in the abdomen, which has been characterized as indicative of decompensation of the portal circulation, appears to mark a critical point in the course of the disease. All of the 112 patients of this group had ascites already at the time of registration at the clinic and presented typical examples of the ascitic stage of portal cirrhosis. From all of the cases in the group other causes of ascites could be definitely excluded, in addition, the diagnosis was confirmed in half of the cases by surgical exploration or necropsy. Eighty-two of the patients were males and forty were females; sixty per cent were between the ages of forty and sixty years.

A careful inquiry was made into the early symptoms noted in each case and the results are presented in figure 2. It is significant that approximately sixty per cent of the patients had suffered from various gastro-intestinal symptoms for from two weeks

to twenty years prior to the development of ascites. The average duration of these symptoms was considerably more than a year. Loss of strength was common, but loss of weight does not seem to have been conspicuous until shortly before the appearance of ascites. As in the group without ascites about a fourth of the patients gave histories of slight, intermittent, painless jaundice, often associated with diarrhea, vomiting, and abdominal cramps. Hematemesis was noted as an early symptom in less than ten per cent of cases. Ascites developed suddenly in about eighteen per cent. In six cases, an enlarged liver or spleen had been found or a definite surgical diagnosis of cirrhosis had been made from two to ten years before the development of ascites.

The early symptoms were in contrast to those which were complained of at the time the patient registered at the clinic. After the appearance of ascites loss of strength and weight

were much more striking and abdominal pain or distress was complained of by about half of the patients. Jaundice was present in thirty-eight instances. Gastro-intestinal bleeding was twice as common as in the early stages of the disease.

The physical evidences of the decompensated stage of hepatic cirrhosis are too well known to require particular comment. The combination of characteristic "hepatic" facies, slight jaundice, ascites, edema, and visible collateral circulation, constitutes a picture familiar to all clinicians. Certain incidental features are not so well known. Forty-seven of the patients with ascites had one or more hernias, five had two, and one patient had three. This high incidence is surprising when one considers that in other types of ascites or abdominal enlargement hernia is less frequently encountered.

About fifty per cent of the 112 patients of this subgroup had more or

FIG 2 Early symptoms of portal cirrhosis in cases in which ascites develop

less marked collateral venous circulation over the abdomen, lower part of the thorax, or lumbar region. In one case, the size of the peri-umbilical veins was striking, in another, a very large vein was noted over the thorax, and appeared to terminate in the axilla (figure 3)

A palpable liver was noted in sixty per cent of the 112 cases. The degree of enlargement varied greatly at different times in individual cases, and in some cases the size appeared to decrease while the patient was under observation. The spleen was palpable in about forty per cent of the cases. From a consideration of data obtained at operation and at necropsy in this group however, it would appear that clinical conceptions of the size of the liver and spleen may not be accurate, particularly when ascites is present.

LABORATORY TESTS

The laboratory studies require only brief mention. What is to be said about them applies to the series of 112

cases with ascites. Scanty and highly concentrated urine was the rule. Examination of the urine for urobilin and urobilinogen gave variable results which seemed to depend on the presence or absence of slight jaundice. About twenty-five per cent of the patients had slightly elevated values for serum bilirubin at some time while they were under observation. Deep jaundice, however, was rare. In ten cases, the bile acids in the serum were determined by the method of Aldrich,¹⁷ and in all normal values were found.

In about forty per cent of the cases there was a definite anemia, with hemoglobin of fifty per cent or less. The characteristics of the blood in general corresponded to those previously described by King.²⁴ The values for blood sugar and blood urea were normal in practically all cases, although in fifteen of the group the concentration of urea in the blood was elevated at some time in the course of treatment. In one case, and on one occasion only, a very low value for

blood urea (4 mg in each 100 c.c.) was encountered. In two cases post-operative hypoglycemia was noted. Following the appearance of papers by Minot and Cutler,³⁴ and Ellsworth,¹¹ determinations of guanidine in the blood were made in a number of cases, but striking or significant changes were not noted.

The tests of hepatic function with bromsulphalein or phenoltetrachlorophthalein proved their dependability in this series of cases, as in other series of cases reported from the clinic.¹⁸ These tests were done in eighty-seven cases, and in eighty, positive results were obtained. The results of repeated tests of hepatic function were remarkably constant in any given case, providing jaundice was not present. In exceptional instances there was reduction in the degree of retention of dye as the patient improved. This was particularly true when the original cause of hepatic injury was discovered and effectively treated.

Tests of hepatic function by means of dyes appear to be influenced by three factors: (1) the amount of blood coming to the liver through the portal vein and the hepatic artery, (2) the presence or absence of jaundice, and (3) the amount of functioning hepatic tissue. The degree of retention of dye seems to indicate, in a general way, the degree of parenchymal injury, although clinically the degree of retention of dye could not be correlated with the size of the liver, the degree of ascites, or the degree of toxemia presented by the patient. The prognostic value of the test, however, appears to be considerable, since patients with retention of dye, graded

three or four, on the average, pursue a much less favorable course than those with low degrees of retention.

CAUSE OF SYMPTOMS OF PORTAL CIRRHOSIS WITH ASCITES

It seems advisable to review briefly what is known of the serious symptoms and signs of portal cirrhosis in the ascitic stage. Pain may be of enteric origin, although other causes cannot be eliminated.²⁸ Jaundice is apparently an expression of hepatic parenchymal degeneration. Hemorrhage appears to be due most frequently to leakage from esophageal varices. These appear to be present in every case of cirrhosis, although they are not always demonstrable at necropsy, since special injection technique may be required to disclose them. In life they have been demonstrated rarely, since esophagoscopy has been performed only infrequently in this group of cases. Gilbert¹⁶ and his associates have performed this procedure in twelve cases, and have found dilated esophageal veins in all. Wolf¹¹ has demonstrated esophageal varices by roentgenologic methods in two cases, and Kirklin and Moersch¹ are reporting a case in which such varices were demonstrated by roentgenologic methods and by esophagoscopy.

The factors which favor bleeding from these varices are not known. Physical exertion seems to precipitate the hemorrhage in some cases. In others, the hasty eating of coarse foods apparently has provoked hemorrhage. A number of patients bled after paracentesis and after operation. Many other patients stated that their

bleeding had begun when they were asleep, a fact that may be explained on the basis of venous stasis and congestion. It is, of course, generally recognized that a hemorrhagic tendency of unknown nature and variable severity exists in hepatic disease of all types, and it is certainly a common accompaniment of portal cirrhosis, although laboratory studies on the coagulating properties of blood in this disease may not always give conclusive proof of the hemorrhagic tendency.

The cause of the ascites has been debated since time immemorial, and a great many possible explanations have been brought forward. Portal obstruction alone is not sufficient, and other factors must be involved. Herick⁹ has expressed the belief that ascites appears when vascular injury has reached such a point that the pressure in the hepatic artery can affect that in the portal system. Feissinger¹² has attributed it to acute degenerative changes and swelling of the hepatic cells, and secondary occlusion of the portal capillaries which are confined in an elastic framework. Bollman⁶ has demonstrated the effect of dietary factors which could hardly operate except through their effect on the hepatic cell or by peritoneal irritation. Occasionally ascites will develop from portal thrombosis. Mann¹¹ has expressed the belief that four factors are involved: (1) interference with portal circulation, (2) lack of absorption from the peritoneal surfaces and from the intestines, (3) peritoneal irritation, and (4) reduction in the amount of functioning liver tissue. It has also been suggested that to a certain extent ascites may be due to the

hepatic cells may interfere with the renal elimination of water.

Little, if anything, is known about the nature of the so-called hepatic coma which is so frequently a terminal event in portal cirrhosis. It is generally agreed that the chemistry of the blood is not altered as it is in the hepatectomized animal, although in occasional cases there is hypoglycemia. Failure of the detoxifying function of the liver has been regarded as significant. Becher² has noted an increase in the amount of phenol and phenol derivatives in the blood of patients with cirrhosis of the liver, which he has attributed to failure of this function.

PROGNOSIS

The prognosis of portal cirrhosis is grave in any stage of the disease. As was previously noted, the mortality in the preascitic stage is high, even in cases in which the disease is discovered accidentally at operation. Of the 112 patients in the group with ascites, eighty-four have died. Coma, gastrointestinal hemorrhages, and intercurrent diseases were the principal predisposing causes of death. Six patients died after operations, and the death of four of them was directly attributable to hemorrhage. Twenty-seven patients died at home from causes unknown to the clinic. The average duration of life of the patients was about sixteen months after the appearance of ascites. The twenty-eight patients who are living have survived on an average about thirty-eight months after the development of ascites. These figures, although not encouraging, are better than the

previously given in the older literature, a point which is demonstrated in figure 4. Formerly the average duration of life after the development of ascites was from two to five months. The longer period of survival of the patients in the group considered in this paper may possibly be attributed to recent improvements in the medical treatment of cirrhosis, but such factors as earlier diagnosis and treatment, a lower incidence of marked alcoholism, and a high degree of intelligent cooperation on the part of many of the patients must also be taken into account. The prognosis is obviously better in the occasional case in which the causes can be found and eradicated.

The prognosis in individual cases can be determined roughly by four

factors: (1) the degree of retention of dye, (2) the response to treatment with diuretics, (3) the general state of nutrition of the patient, and (4) the presence or absence of complicating disease. Patients with low degrees of retention of dye, who respond favorably to administration of diuretics, appear to do particularly well. The same may be said of patients who remain in good nutrition and who are willing to make the necessary adjustments in their manner of living. Complicating diseases, particularly those of an infectious nature, appear to add greatly to the gravity of the situation.

OBSERVATIONS AT NECROPSY

The pathologic changes seen in cases in which patients have died with portal cirrhosis have been described

FIG. 4. Average duration of life in portal cirrhosis with ascites: upper two lines—cases seen at The Mayo Clinic, 1924 to 1929 inclusive; lowest line—cases noted in the literature prior to 1921.

often For the sake of completeness, I include here the significant features disclosed in a group of recent postmortem examinations made at the clinic, in the course of the years 1924 to 1930 inclusive A decrease in the size and weight of the liver is fairly uniform in this series, as may be noted in figure 5 The size of the liver does not seem to bear any relationship to the weight of the spleen or to other changes found at necropsy In Nissen's¹⁶ series, reported ten years ago, the average life of the patients was shorter, and the average weight of the liver was considerably higher

Collateral circulation was demonstrable in practically all cases In several, the omentum was adherent to the abdominal wall and represented spon-

taneous omentopexy Esophageal varices were present in every instance, and in at least one-third of the cases there was evidence of recent bleeding into the gastro-intestinal tract In three cases intraperitoneal hemorrhage was noted Edema at various points of the gastro-intestinal tract was common, often associated with congestion and small regions of superficial ulceration Chronic gastric or duodenal ulcers, either healed or active, were present in about twenty per cent of cases Fibrosis of the pancreas was noted in more than one-third of the group Cholelithiasis was found in five cases, chronic cholecystitis without stones was noted in twelve, and marked edema of the gallbladder in two

Active tuberculosis was not found in any case in this group, although healed lesions of tuberculosis were fairly common. Hydrothorax was found in an occasional case and terminal bronchopneumonia was present in about fifteen per cent. Anatomic changes in the kidney were uncommon. This seems significant when it is recalled that many of these patients had failed to respond to diuretics, either at the clinic or elsewhere.

TREATMENT

In the past, the treatment of portal cirrhosis has been directed largely toward removal of ascitic fluid, and there are reasons for believing that the strenuous efforts made in this direction have done much to shorten the life of these patients. It must be admitted, however, that many patients are sufficiently improved by removal of fluid to make the therapeutic attempts along these lines attractive. When one considers the natural course of cirrhosis, and the experimental evidence showing that ascites is an extreme terminal development rather than an essential element of the disease, the possible fallacy of giving ascites first consideration in treatment is obvious. This was noted by Morgagni³⁵ who asks this significant question: "Why should the physician trouble with very strong and violent remedies those in regard to whom he ought to think only how to preserve their lives as long as possible instead of attempting to cure their disorder?"

Treatment in portal cirrhosis should be directed primarily toward the detection and eradication of etiologic

factors, and secondarily, toward the maintenance of the functional integrity of the hepatic cell. It is unnecessary to emphasize the fact that treatment antedating the development of ascites is highly desirable. Success will depend largely on the physician's ability to do these things, and, in the later stages, on the ability of the patient to respond to treatment by diuretics or to surgical measures.

The details of treatment in this group of 112 patients with decompensated portal cirrhosis have been considered elsewhere.⁹ Prior to registration at The Mayo Clinic, treatment of these patients had been confined largely to paracentesis. A few patients had been given diuretics. After registration, eighty-four of the 112 patients were treated with mercurial diuretics combined with ammonium salts in large doses, after the method described by Rowntree, Barrier and Keith.⁴⁵ All of these patients were given a high carbohydrate diet, and water and salt were markedly restricted. About eighty per cent of the patients in this group responded satisfactorily to treatment; in forty-seven per cent the results might be classified as excellent, in about thirty-two per cent they were moderately satisfactory, and in twenty-one per cent they were poor.

Not all patients are suitable for diuretic treatment, and careful selection must be made. Patients with ascites of long standing may be resistant to even the most vigorous treatment, and too much must not be expected of diuretics in the late stages of the disease. In many instances as the disease progresses there is gradual

decline in the effectiveness of diuretics. Elderly and cachectic patients should be treated with caution, if at all. In the presence of marked jaundice, diuretic treatment is rarely effective, and should be employed only with great care. Active gastro-intestinal bleeding and mental symptoms also appear to be contra-indications.

Toxic reactions to treatment do not necessarily preclude further treatment, but they do emphasize the necessity for proceeding cautiously. Feissinger and others¹ have stated that if patients are not improving from the use of diuretics they are probably getting worse, a point which has been substantiated in my experience. Frequent paracentesis does not furnish an adequate substitute for treatment by diuretics. The intervals between tapping become progressively shorter and as White²⁰ has remarked, many patients do not survive even the second paracentesis. The effect of diuretics seems to be more permanent, for reasons which are unexplained. Saxl¹⁸ and Feissinger¹ expressed the belief that in selected cases mercurial preparations stimulate hepatic regeneration and improve hepatic function. The best protective measure in the presence of hepatic lesions both experimental and clinical is the administration of carbohydrate by mouth and by vein. The daily use of glucose intravenously has given excellent results in the treatment of impending hepatic insufficiency, and deserves more general trial. Concentrated solutions of glucose (from 20 to 30 per cent) are particularly useful because of the small amount of fluid introduced. Such solutions may be given

daily, in amounts of from 250 to 500 c.c., without apparent harm or discomfort to the patient, and in some instances they appear to have been life saving. The giving of insulin at the same time does not seem to be an advantage. When diuretics do not act, it is usually advisable to begin the forced administration of glycogen-forming substances and to perform paracentesis as often as necessary, to control the accumulation of fluid.

Operations. Surgical measures in cirrhosis have been designated to relieve the patient of ascites by mechanical means, to establish additional connections between the portal and the general circulation, to reduce the load on an overburdened portal circulation, and finally to eliminate channels of collateral circulation at vulnerable points, such as in the lower part of the esophagus. All of these procedures have given variable results and have not been entirely successful. The experience of surgeons in this field has been well covered by the papers of Hughson,²² Hopfinger,²¹ and W. I. Mayo.¹⁷ The various procedures which have been employed are represented schematically in figure 6. The Talma-Morrison omentopexy which has been so widely used, is accompanied by high immediate mortality, but it has given some fairly good results. Reisman¹⁹ described two cases in which the patients were apparently cured by this means and some gratifying results have been reported from the Mayo Clinic. Hughson's figures are not encouraging. Hopfinger expressed the thought that not more than one third of patients derive any

benefit from this operation, and this has been the experience of Eliot and Colp¹⁰

Splenectomy, which produces such excellent results in Banti's disease, does not appear to be so effective in portal cirrhosis. The differentiation between Banti's disease and portal cirrhosis is often difficult, and doubtless the two diseases are frequently confused. There appears to be a group of young persons with marked splenomegaly and hematemesis who

are benefited by removal of the spleen, and in them definite portal cirrhosis is frequently found at operation. It will be noted, in figure 5, that the average splenic weight in twenty-eight cases of cirrhosis in which the patients came to necropsy was low, and it is difficult to see how removal of these spleens could have altered greatly the course of the hepatic disease. Splenectomy, of course removes a substantial burden from the portal circulation, but the surgical

FIG 6 Surgical procedures in portal cirrhosis. (1) Talma-Morrison omentopexy, (2) splenectomy, (3) ligation of coronary veins, (4) Eck fistula, (5) anastomosis of inferior mesenteric vein to vena cava, (6) transplantation of saphenous vein into peritoneal cavity.

risk is considerable and the end-results are not altogether encouraging

Ligation of the coronary veins of the stomach, either alone or in combination with splenectomy or omentopexy, has been done successfully⁴⁶ in a few selected cases, with good results. The operation is primarily directed toward the control of bleeding from esophageal varices and deserves a more extended trial. Various forms of anastomosis between the portal and venous circulation have been advocated, notably the Eck fistula⁴⁹ and anastomosis between the mesenteric vein and the vena cava.⁵ Some good results have been reported, but in many cases sufficient connection between the portal and general circulation exists to render these operations more or less unnecessary. Various mechanical measures also have been proposed to rid the patient of ascites. Of these the most popular seems to be the method of Ruotte,¹⁷ who has transplanted the saphenous vein into the peritoneal cavity. Success has been reported in some cases¹¹ and the operation recently has been advocated again by Franke.¹¹

Most surgeons who have had large experience with the surgical treatment of portal cirrhosis feel that all types of operative treatment are carried out too late to be of much benefit to the patient. At the present time it is the general practice of physicians to try a variety of remedies before considering surgery. Knowledge of the usual course of cirrhosis makes the inadvisability of this plan obvious. If patients do not react to diuretics and are progressively failing, it is unlikely that they will experience any relief

from operation. If patients are young, in good condition and respond well to diuretics, omentopexy or splenectomy should be seriously considered. If hematemesis is a prominent feature, ligation of the coronary veins may be carried out with good prospects of relief. Even with the best selection of cases the surgical risk is not to be disregarded, and one must be prepared for many discouraging failures.

SUMMARY

In reviewing a group of approximately 400 patients with portal cirrhosis in all recognizable stages of the disease, the chronicity and latency of the condition before the development of ascites is striking. Of patients with cirrhosis who are seen, the number of those who are in the preascitic stage is perhaps twice as great as the number of those who are in the ascitic stage. In the earlier stages, when these stages can be detected, eradication of causative factors may stop the progress of the disease. This is particularly true when alcoholism, syphilis, cholelithic disease, or chemical poisoning are causes.

The early symptoms are largely those of vague indigestion, intermittent jaundice, or gastro-intestinal bleeding, and in cases in which these complaints are made, tests of hepatic function may reveal the diagnosis. The earlier recognition of cirrhosis is highly to be desired because in the earlier stages, arrest of the process is theoretically possible.

The appearance of ascites marks a critical point and indicates the end stage of a lesion of ominous portents of significance. Treatment in the

stage has been facilitated by the use of mercurial diuretics, and review of the results obtained in a series of 112 cases with ascites shows longer duration of life than in comparable groups

reported in the literature. The indications for medical and surgical treatment, and the limitations of each, are considered with reference to the known course of the disease.

Hereditary Ectodermal Dysplasia of the Anhidrotic Type*

By WILLIAM H. GORDON, M.D., F.A.C.P., and ROBERT C.
JAMIESON, M.D., *Detroit, Mich*

IN making a report of this case which we feel belongs to the group described by Goeckermann⁶ in 1920, MacKee and Andrews¹² in 1924, Weech²¹ in 1929 and Jean Smith¹⁸ in 1929, it is deemed hardly necessary to review in detail the cases comprising the list that has been so ably brought up to date by the authors mentioned.

We therefore will give a detailed description of this case and give tables of the chronology and clinical and pathological features to conform

to those in MacKee and Andrews¹² work in order to give uniformity to the reports of cases to date.

This chronological table is compiled from those given by MacKee and Andrews¹² and Jean Smith¹⁸ with the addition of two cases described by Oliver and Gilbert¹⁴ in 1926. After a study of the cases reported by Mackay and Davidson¹³ as "Congenital Ectodermal Defect", they were not considered to have a place in this group which Weech²¹ terms Hereditary Ectodermal Dysplasia of the Anhidrotic Type. Jean Smith¹⁸ believes this a better term for the anomaly.

*Received for publication April 1, 1931

and we agree with her reasons for the use of the title

MacKay and Davidson's¹³ cases showed dystrophy of the hair and nails only, with no change in the sweat or sebaceous glands and none of the other features of the anhidrotic type. These authors present a genealogical chart of affected persons in five generations in which transmission by both sexes is shown.

To this group we feel should be added Clouston's³ analysis of 119 cases in six generations, reported under the title of "Hereditary Ectodermal Dystrophy." These are all dystrophies of the hair and nails and Clouston³ differentiates this type from the anhidrotic type. He found in this group cases of keratoderma palmaris et plantaris and thinks they are residual forms of a disappearing dystrophy. This type involves the epidermis itself, the hair, nails, sebaceous glands and to some extent the sweat glands.

It is possible that there is some relation between the two groups.

The two cases reported by Oliver and Gilbert,¹⁵ while not having all the major defects, are considered by the authors to belong to this group.

CASE REPORT

Patient, G F, female, aged 17, native of Detroit, born of Russian Jewish parents, has been under our care for ten years. Her chief complaint was deficient growth of hair and teeth and inability to sweat. Difficulty in working during hot weather.

Present Illness Patient has noted that her hair was sparse very early and sought medical advice at that time. She was under treatment for a very short time when she discontinued same. In May, 1930, she again sought medical advice in an attempt to remedy her complaints.

Family History Father is living and well. Mother died of heart disease and diabetes at 43. Two sisters and one brother are living and well. No history of a similar disease in the family. One sister age 25, has absence of a few upper teeth with one peg-shaped upper left cuspid. Paternal uncle has manic-depressive psychosis.

Past History The patient has had measles, chickenpox and scarlet fever. Tonsillectomy was done ten years ago. In the past two years her cervical glands became swollen and at that time were painful. In winter these glands swell up once a month and remain so for a few days. She has frequent nose bleeds. There is a history of convulsions until ten months of age. She was delivered by instruments. History by systems is negative.

Physical Examination Height five feet, five inches. Weight, 124½ pounds. Blood pressure, 120/70. There is a peculiar lack of hair on scalp and face (eye-brows), axillae and pubis. Hair which is present over scalp and pubis has appearance of lanugo hair and is very scant, fine, dry and almost crisp and close to skin. Skin around upper and lower eyelids is pigmented. Lips are thickened. Skin is dry, cool and scaly in places. Face presents freckles. Forearms show faint brownish pigmentation over extensor surface. Eyebrows are lacking excepting a few hairs at midline. There is no hair in the axillae or on forearms and legs and but few hairs on mons Veneris. The eyes are small and set close together. The pupils are large, round and equal react to light and accommodation. The nose is of a marked saddle-shape and the nares small. Foul odor of ozena comes from the nose and upon examination with speculum the septum is found to be partially destroyed. Grey necrotic material is present. The mouth is narrow, the lips prominent and thick and the mouth is poorly kept. The teeth are in poor condition. Though but one has been extracted one notes the absence of a large number. Those that are present are of a peculiar shape (peg-shaped) and misplaced so that it is impossible to tell which are missing. The buccal membranes appear to be healthy. The cervical lymphatic tonsil tag. The neck glands are negative.

TABLE III
MICROSCOPICAL FINDINGS IN SKIN IN REPORTED CASES

	Oliver and Gilbert ¹⁴	Weech ²⁴	Weech ²⁴	J Smith ¹⁸	Falconer ⁴	Gordon and Jamieson
Location	none reported	none reported	none reported	anterior chest and axillary line level with nipples	thumb	inguinal region
Sweat glands	none reported	none reported	none reported	none	none	none
Hair follicles and arrectores	none reported	none reported	none reported	none	none	none
Sebaceous glands	none reported	none reported	none reported	none	none	none
Epidermis	none reported	none reported	none reported	no description	well differentiated and high degree of keratinization	layers normal
Derma	none reported	none reported	none reported	none	normal muscle fibres well developed	normal
Elastica	none reported	none reported	none reported	none		normal

The thyroid shows a small adenoma. The areolae of the breasts are 7 mm in diameter. The breasts are flat and poorly developed so that very little breast tissue can be palpated. Otherwise the chest is negative. The abdomen is normal.

The patient presents a facies of a Mongolian type and looks anything but intelligent but upon questioning her one finds that she is above the average at school. She is seventeen years of age and in the 11th A grade. She plays the piano well. Her voice is husky, dry and squeaky. All *Reflexes* are normal. The arms well formed and shaped, fingers pointed, legs well formed and shaped. On the right knee there is a scar from injury.

Provisional Diagnosis at onset. Congenital lues and Hutchinsonian teeth.

Laboratory Data. Urine negative. *Blood Wassermann negative*, *Spinal fluid Wassermann negative*. Spinal fluid showed a negative cell count. Blood count on May 15, 1930: hemoglobin, 83%, red blood cells,

3,910,000, white blood cells, 16,800 polymorphonuclears, 79% lymphocytes, 14%, eosinophils, 4%, mononuclears 3%. On Oct 6, 1930 the blood count was: hemoglobin, 80%, red blood cells 5,370,000, white blood cells, 9,500, polymorphonuclears, 50%, lymphocytes, 41% mononuclears, 7%, basophils, 1%. The electrocardiogram was normal. Blood chemistry findings on Oct 5, 1928 were as follows: blood sugar, 0.100, N.C.N., 28.6, cholesterol, 136. On Oct 13, 1928 blood sugar, 0.095, Ca 8.4, Phos 2.78. On Oct 17, 1928 uric acid 4.28. B.M.R. Oct 9 1928 minus 11%. Repeated B.M.R. Oct 11 1928 minus 11%. Oct 20 1928, minus 20%. Goetsch skin reaction, Oct 14 1928 normal.

Histologic Description of Skin (Lido J. Wile, M.D., Professor of Dermatology, University of Michigan). The epithelium is about normal in thickness. Here and there on the surface is a patch of hyperkeratosis. The various layers of the epidermis are normal. The stratum granulosum is ill de-

FIG. 2. Pre-operative patient taken in 1950

FIG 3 Side view of patient in 1930

field. The hemalum and eosin specimen shows a fairly dense subcutaneous tissue with considerable fragmentation of the collagen bundles. The striking feature of the subcutaneous tissue is the complete absence of both hair follicles, sebaceous glands, and sweat coils and ducts. The Van Gieson stain shows the collagen bundles well defined, but distinctly fragmented. The subepithelial elastica is well stained, and shows no abnormality. The resorcin-fuchsin, lithium carmine preparation shows the elastica well distributed throughout the section and apparently no diminution or fragmentation of the collagenous bundles, and a complete absence of the entire pilo-sebaceous system and of the sweat coils and ducts.

Description of the Teeth (H. F. Doane, DDS, of Detroit, Michigan). X-ray examination was made on March 24, 1931. This examination consists of eleven intra-oral films. At the present time the upper arch contains seven teeth and the lower arch five teeth. The patient gives a history of having had the lower left molar extracted. So far as can be determined, thir-

teen teeth are all the patient ever developed. None of the teeth which have erupted present the usual anatomic features. The upper right and left molars appear as bicuspid with an extra cusp, that is, the occlusal surface does not present the usual grooves and cusps of a molar. The appearance is very similar to the occlusal surfaces of the bicuspid, with the exception of the fact that there are two buccal cusps instead of one. The tooth occupying the lower right molar region presents anatomical features almost identical with the bicuspid. The roots of all molars appear single, although there is more than one root canal, indicating fused roots instead of the normal bifurcations. The teeth occupying the normal position of the upper central incisors present anatomical features very similar to the upper cuspids. The remaining seven teeth appear as the so-called peg teeth, their crowns being cone-shaped and presenting little or no anatomical marking. The tooth occupying the upper left lateral incisor region appears to be deciduous. At this time, its root is resorbed.

FIG. 1. X-RAY OF UPPER MOLAR AND LOWER MOLAR.

and the tooth is very loose. The enamel of the teeth which have formed and erupted is of usual thickness, but to date no microscopic study of tooth tissue from this patient has been made. Clinically and roentgenographically the structure of the enamel, dentine, pulp chambers and pulp canals appears as usual. Neither the extraoral nor the intraoral films of the patient's jaws reveal any evidence of unerupted teeth, and no tooth buds or malformed tooth tissue is evident. In the upper right bicuspid region we note an area of decreased density which appears to be poorly calcified bone. A similar area, but less extensive, is shown in the upper left bicuspid region. Roentgenologically, the bone in the lower right and left bicuspid regions, where no teeth ever developed, appears somewhat compressed, as compared with the regions in which teeth have developed. Otherwise the body structure of both jaws is quite usual in appearance on X-ray examination.

DISCUSSION OF GENERAL CHANGES FOUND ON SKIN AND APPENDAGES

The hair of the scalp was fine and grew sparsely over the entire scalp. It seemed to be of a normal length but was of soft texture and grew slowly. The eyebrows were lacking except at the inner third where a few hairs were found. The eyelashes were few and scattered along the border of the eyelids.

A few short fine axillary hairs could be detected on close examination as well as a very slight lanugo growth on the body, arms, upper lip and cheeks. This growth was practically invisible without the use of a magnifying glass. Pubic hairs were scanty.

Supraorbital ridges were prominent. No pseudorhagades were found but the vermillion borders of the lips were definite though not marked. The sense of smell and sense of taste were stated to be normal.

The bridge of the nose was depressed in the typical saddle-back formation, a chronic rhinitis was present with an accompanying foul odor. The general impression of the face was that it was of the Mongolian type.

The palms and soles presented many fine criss-crossed lines, were smooth, dry and shiny, giving the feeling of a dry skin tightly stretched over underlying structures. The finger nails and toe nails presented no abnormalities.

In the center of the back over the spine of the interscapular region and also over the scapular areas were three groups of minute papular lesions of non-inflammatory type suggestive of keratosis pilaris.

The entire skin was very white, fine, smooth, soft, glossy, pliable and dry.

SUMMARY

A case is described presenting the major defects of anhidrosis, alopecia, dental aplasia, nasal rhinitis and saddleback nose with absence of sudoriparous apparatus.

Tables are presented with cases reported in the literature in chronological order up to the present time. A tabulation of symptoms of those reported since 1924 and a tabulation of microscopic pathologic findings are also given.

FIG. 1. Photograph of thin

FIG. 6 Higher power magnification of skin. The entire pilosebaceous system is absent.

The Application of a Modified Psychiatric Approach in the Treatment of Certain Gastro-Intestinal Disorders*†

By THODORE H. MORRISON, M.D. F.A.C.P. and SAMUEL MORRISON, M.D. *Baltimore, Md*

IT has long been recognized that a large number of patients who come under the care of the gastro-enterologist are psychoneurotic and one wonders whether the gastro-enterologist is able to treat these patients satisfactorily or whether they can be better cared for by a psychiatrist. A consideration of the type of psychoneurosis, its duration, its status praesens, etc., makes this decision less difficult. In those instances in which the psychoneurosis is very mild and is referred to the gastro-intestinal tract particularly where the patient is fifty years or older, it is our opinion that a more satisfactory outcome can be obtained if the patient is under the control of a capable gastro-enterologist.

A gastro-enterologist should be thoroughly familiar with psychiatric measures if he hopes to succeed in caring for these patients. On the other hand, we are convinced that a capable psychiatrist cannot be expected to be a gastro-enterologist. In either event it is conceded that the individual patient

must be considered primarily but the best and most permanent results according to our experience are obtained by the physician whom we may call the gastro-psychiatrist. The latter sees no reason for unearthing complexes delving into the subconscious and thereby magnifying the patient's troubles. He has no objection to the simultaneous use of both medical and psychotherapeutic forms of treatment. He is not aware of any danger in administering a medicinal treatment to a psychoneurotic nor does he deny its supposed detrimental effect. He does not stress too strongly the "nervous" element in the patient's personality because he knows from experience that little or no benefit is derived from such a procedure. He does not hesitate to treat the disease and to give the patient symptomatic relief while he studies the individual as a whole for he realizes through a long-continued association with these individuals that this plan inspires more profound confidence and that it leads to a so-called cure which is more lasting and less time-consuming. Above all he avoids deception and yet he employs a practical psychotherapy which neither

*From the Gastro-Enterological Clinic of the Department of Medicine, University of Maryland

†Received for publication April 20 1931

stamps the patient as psychopathic, nor allows him to consider himself entirely normal

How does the gastro-psychiatrist study his cases? He, of course, realizes that treatment, as well as disease, cannot be standardized. He therefore makes the usual complete study including a good history, a brief personality study, a physical examination, the indicated laboratory procedures and any special studies which seem advisable. All these he considers essential parts of psychotherapeutics. If after such a thorough study no organic basis for the patient's symptomatology is noted he can offer reassurance in a manner which is most convincing. In this way he not only gains the patient's confidence but makes the first step in the needed reeducation. In his conversations much is learned concerning the patient's reactions and this aids in pointing out the correct plan of treatment. The symptoms are genuine and if drugs will relieve these, they are temporarily employed without fear of dire consequences. Rest, diet, exercise, occupational therapy are utilized as indicated. Where hospitalization seems advisable a general hospital or sanatorium is selected depending upon the status of the patient. Sometimes a change in environment alone is a most valuable therapeutic measure. It is surprising how willing a patient is to cooperate with a gastro-psychiatrist and how frequently the former readily believes that "nervousness" is the cause of his physical disturbance. In only a few cases is it necessary to resort to the use of drugs. The patient is reassured that his symptoms are not due to a serious organic disease and that they are not a reflection of his character. He is encouraged to face his physical condition with confidence and to follow the plan of treatment suggested by the physician.

relationship between physician and patient the factors concerned in the latter's maladjustment are unraveled with much less difficulty. We have seen the most sensitive patients gradually become desensitized by such an approach and more extraordinary is the fact that the sequence of events leading up to the present illness explain themselves automatically. There is, however, a certain group of individuals who do not respond so well. These are usually cases who have consulted many physicians, going from one to another without allowing time for sympathetic understanding and adequate treatment. However, in some instances even such individuals have been helped by the procedure which we advocate. Often the mental effect of a complete examination with an explanation of the condition and reassurance results in a "cure." For example, this occurred in many patients who presented themselves with a cancer phobia and in whom this idea was not only recognized early but dispelled as a result of a complete study.

In many of our cases we have observed that with individuals who lack average intelligence the response to psychotherapeutic measures is unsatisfactory, whereas the treatment of a symptom or an organic condition (if that exists) is impressive and in itself becomes an efficient psychic measure. For instance, the mere application of a support in a patient with enteropneosis or pendulous abdomen even though these conditions may have little to do with the production of symptoms may be a great physical comfort that results in a marked improvement in the patient's condition. This is especially true in cases where the patient is unable to understand the nature of his condition and the physician is unable to explain it in a way that the patient can understand. In such cases the patient is reassured that his symptoms are not due to a serious organic disease and that they are not a reflection of his character. He is encouraged to face his physical condition with confidence and to follow the plan of treatment suggested by the physician.

other examples could be noted but the idea which we wish to emphasize is that this group does not lend itself to pure psychic appeal for there is little to appeal to. On the other hand, these individuals respond to medicine and physiotherapy because these measures inherently carry with them suggestive properties.

Witness this instance, related by Bland Sutton,¹ of a psychiatrist who made excellent use of a frog in the following circumstance. "A thin and foolish woman believed she had accidentally swallowed a frog and that her thinness was due to the frog eating the food in her stomach. In order to dispel the illusion the doctor gave the patient an emetic and during the vomiting he slipped a frog into the basin. When the patient saw the frog her joy was great, but in a few minutes her depression returned. 'Oh!' she exclaimed, 'I am sure this frog has left some young ones in my stomach.' The doctor looked wise, pulled out his magnifying glass, and after critically examining the frog said unto the patient, 'Fear not, this frog has not left any froglets inside you, behold, it is a male!' The patient was quite satisfied, became happy and in a few months was plump again. She was not a naturalist, and therefore ignorant of the fact that it is difficult to tell the sex of frogs by mere inspection except at the breeding season."

We should like to direct attention to another group of cases in which any form of psycho-analysis is contraindicated. When a patient is examined one often realizes that no progress will be made unless personal matters are investigated. However,

there have been many individuals who consulted us after they had bitterly resented what they deemed irrelevant and unnecessary questioning directed towards their private affairs at the hands of psychiatrists. We have seldom found it necessary to inquire into sexual relationships, marital incompatibilities, financial affairs, social and religious difficulties. In some cases the patient is aware of an underlying maladjustment and is able to combat it if his mental attitude is changed through a process of reassurance, encouragement and relief of symptoms. In other instances, the individual fails to recognize any underlying psychological causes and not only seeks but insists that a physical basis be discovered. In this group a tactful, delicate and sympathetic approach opens up more avenues of willing discussion than could be obtained by the immediate attack upon repressions, inhibitions, the subconscious, and so forth. It is certain that every one of us has built up a defense mechanism which is the basis upon which our adjustments to our environments rest. To shatter these structures is dangerous. They are the buildings resulting from years of construction, tampering with them is unwarranted. Psychiatrists often seem unaware of this fact.

It is generally admitted, as Reynolds² states that a fundamental principle of the treatment of neurosis is based upon an explanation to the patient of the evolution of his nervous symptoms from their original sources. In our experience there are a large group of cases in which such explanations are best omitted. It is proper to ascertain the causative factors in-

volved in each individual case but it is not well to break down a moderately substantial foundation because one feels that the patient should conform with the majority. If we learn that the neurosis is dependent upon certain sexual problems, certain environmental conditions, certain physical handicaps, etc., these can be adjusted in many instances without the patient's knowledge and with much better effect. Many of these individuals gradually become self-explainers and their pride in having discovered and treated themselves is in itself a great conquest. Like the obstetrician we must preach "*noli me tangere*" in this group of cases which will become more and more well defined as time proceeds. We realize all the old arguments about the necessity for strengthening individuals with neuropathic streaks, inferiority complexes and unstable nervous equilibria but we know from an ever growing experience, that the best procedure is not to have the patient become conscious of his shortcomings.

Preventive medicine³ plays its psychiatric rôle which is concerned among numerous other things, with the routine and regular overhauling of the type of the patient with whom we are concerned. It is on this account that we advise our patients to visit us at regular intervals. After all, who can determine exactly where the normal limits stop and the abnormal begin, where, for example, the micro-manic-depressive (Overstreet⁴) becomes the manic-depressive. If we are indulging in such vagaries let us give the patient the benefit of the doubt and let us not convince him and ourselves that he

is mentally sick without due evidence. Just as the psychiatrist errs on his side, so the internist, as Reynolds remarks, "is liable to fail if he does not study carefully all the features of the case before starting to treat it." "The difficulty" he continues, "is that the medical practitioner is in danger of becoming so absorbed in the treatment of any obvious organic pathology that he may fail to pay attention to the neurotic symptoms which are its result. On the other hand, if the neurotic element is predominant, it is equally easy to overlook the apparently trivial physical abnormalities which may have been contributory factors in the disturbance of the nervous equilibrium. In order to steer a middle course between these two common errors, it is well to assume that every case has both an organic and a functional element."

It is generally known that most psychopathic persons with gastro-intestinal complaints (as well as society in general) fear the stigma of having any professional contact with a psychiatrist. Certainly this reaction should not exist but since it does, it is best to recognize it. We agree with Alvarez⁵ that one must be fitted temperamentally for the problem presented by these patients. Since the gastro-psychiatrist is familiar with certain syndromes in his specialty it is more probable that he can evaluate the symptom-complexes and plan a rational form of treatment suited to the individual. He certainly realizes that there is a large group of cases in which the mechanism of the affection must be explained in order to obtain satisfactory results. Such an example

may be present in the following instance taken from Oliver⁶ "When a woman who has had phobia of cancer all her life and who has restricted her diet so that she is skin and bone because she has an idea that rough food irritates the stomach and produces cancer there,—when she can be brought to realize that her mind has been sensitized to the fear of cancer because of her distressing experiences with a beloved father who died of it—why, you have already robbed her phobia of a good part of its nameless overshadowing horror" He is also aware of those cases in which patients substitute one obsession, one disease, one anxiety for another. Jelliffe⁷ has called attention to instances in which cures of various "diseases" were obtained sometimes with the aid of surgery only to have another and often less vulnerable affection arise. It must be understood that this method of treatment is offered only in a certain selected group of cases. There are patients with whom one must insist on the mental basis of the affection. Care must always be taken, however, not to plunge the patient into hypochondriasis (Dubois⁸) and one must always have "sized-up the situation" before proceeding in this manner.

To make our position clear, we do not claim a cure-all, we simply offer a method, not different in kind but in principle. In brief, we do not believe that the majority of these gastro-psychoneurotics are best treated by psychiatrists since from the very beginning the former are antagonistic to psychiatrists and where antagonism exists good therapeutic results are wanting. In the treatment we aim as

far as possible, at prompt symptomatic relief. The relief of symptoms leads to a more pliant mental and physical attitude. The fear with which certain psychiatrists administer drugs is commendable in some cases but not, as a general rule, in gastric neuroses. Gastric symptoms can be relieved without the danger of formation of drug habits or other untoward effects.

In order to illustrate more clearly this modified medical and psychiatric approach 200 consecutive gastro-intestinal cases in our clinic were studied. Of these, fifty showed etiologic factors which were definitely psychogenic while in the rest the nervous element was more or less prominent. In every instance, however, the chief complaint was referred to the gastro-intestinal tract. Each patient was subjected to the complete study already mentioned, nothing was assumed. Upon the basis of this examination treatment was instituted.

A few abstracts of illustrative cases follow.

Case I J. L. S., male, (a salesman) aged 60, complained of "stomach trouble and nervousness" of two years duration. The patient was aware of the fact that his mother had died of hypertensive heart disease. In the past he had had the usual childhood diseases with no complications but about ten years ago, following a so-called "mild stroke", he became very weak requiring about three months before he fully regained his faculties. A review of the systems discloses the following important data—nocturia, three or four times very nervous, some insomnia, occasional spell of dizziness and weakness, tires quickly, has many obsessions. Little except the enumeration of some vague digestive symptoms could be learned of the present illness. In other words there was a gastro-intestinal fixation.

On physical examination, the general appearance was one of depression in a well nourished and well-developed elderly man. Briefly, the positive findings were dilated pupils reacting normally, ophthalmoscopic examination normal, lungs normal. The heart was normal in size, the sounds were regular, loud and forceful. Blood pressure 200/120, with no constant associated symptoms. The radials were tortuous and moderately thickened. Abdomen normal. Reflexes normal. The mental examination disclosed many traits of the parergastic reaction type but anxiety neurosis seemed more likely. The urine showed one plus albumin, three plus glucose, a few hyaline casts and white blood cells. Other laboratory examinations were normal.

Our impressions were arteriosclerosis, hypertension, anxiety neurosis, questionable chronic nephritis and questionable diabetes mellitus. Hospitalization was advised. Further studies showed the "diabetes" to be of the nature of renal glycosuria, while no evidence of kidney damage was adduced.

The patient was seen daily, treated symptomatically, spoken to rationally and semi-analytically. Under the administration of mild hypnotics he rested quietly. Gradually his obsessions became less marked. At the same time he began to realize that his principal difficulties were due to "nervous" factors. As far as allowable we stressed his physical fitness, creating simultaneously a restful, reassuring environment and relief of symptoms. The patient, on the other hand, proceeded a step further and diagnosed his case "nervousness". Today, six months later, this man is back in business, working efficiently. He recalls that he was "slightly mentally ill" and is very thankful that we had prevented his relatives from sending him to a mental hospital. It is very unlikely that this patient will have another "nervous breakdown" but should this happen he will certainly seek immediate aid. At the age of 60 he is made fit to work in a certain environment by a mild sort of treatment lasting four weeks.

Case II G. N. C., female, student, aged seventeen years, complained of "gas on stomach" and dizziness. The family and past histories are essentially non-contribu-

tory. The present illness dates back four years when belching was first noticed. For two years there were exacerbations and remissions but gradually the belching became almost continuous and this with a sense of dizziness and emotional instability have persisted to the present time. The physical examination was normal in every detail. The urine and blood were normal. The stool showed two plus mucus. She was unable to swallow the tube for a gastric analysis. X-ray studies disclosed no organic defects, the pylorus was spastic and the colon markedly prolapsed and spastic. In a casual but quite thorough mental examination no alarming findings were noted.

Our impressions were aerophagia, nervous indigestion, and a spastic gastro-intestinal tract. The patient was placed on a schedule of exercises with rest periods and a prescribed dietary regime. In addition she was given certain medicinal preparations combining sedative and antispasmodic properties. Aerophagy was explained to her. Psychotherapy was made to appear incidental.

Under monthly observations a steady gain in weight has been noticed, she has become more stable emotionally and as she remarks, "feels almost well". No attempt was made to blame the entire condition on nervousness although the mechanism of aerophagia was explained in detail. The medications are gradually being reduced but without their psychic as well as medicinal effects, we feel certain that our success in this case would have been much less marked. The "cures" are not temporary since the patient returns at appointed intervals for a check-up and is not discharged until she has a well-established understanding of her difficulties. She is convinced that no organic disease exists and as each visit culminates she realizes more and more that hers is a functional abnormality and gradually she concludes that it depends upon her emotions. The patient credits herself with this discovery and in this attitude lies strength. If the usual psychiatric approach were attempted in a reaction pattern of this kind the problem would have been much more difficult even if the patient's cooperation were taken for granted.

Case III R B, male, shoe-merchant, aged 31 years, complained of constipation and "stomach trouble" characterized by "panicky feelings" and nausea. The family history was non-contributory. In the past there have been four operations over a period of nineteen years. The patient has always been of a highstrung, excitable and unstable nature smoking excessively and imbibing alcoholic beverages occasionally. The present illness is said to have begun three years ago when it was noticed that an already marked constipation was becoming more severe. Symptoms of dizziness, palpitation, "spots before eyes" and general unsteadiness were experienced, and the patient believed he was slowly being poisoned through intestinal stasis. Depression was well on its way but due to certain business matters his mind was occupied for some months. He managed to get along, building symptom upon symptom until six weeks ago when, following the extraction of a tooth, there was a little more than the usual amount of bleeding. He became extremely nervous and apprehensive, a multiplicity of symptoms appeared, his constipation became more uncontrollable than it had ever been, pains and aches were experienced throughout the abdomen, and nausea and loss of weight were noticed. He was on the verge of a mental collapse when seen.

On physical examination he was found to be of asthenic habitus, well developed but only moderately well nourished. He appeared worried and depressed. The head, heart and lungs were found to be normal. Blood pressure, 120/80. Pulse, 90. The abdomen was soft, semi-relaxed and with the exception of a hernial repair scar in the left inguinal region presented no abnormalities. The genitalia, extremities, skin, etc., were normal. Reflexes were very active. The urine and blood examinations were normal. The stool contained a considerable amount of mucus. The Ewald test breakfast showed a total acidity of 82, free hydrochloric acid, 65. The Wassermann reaction (blood) was negative, phenol-sulphonephthalein test showed 55 per cent excretion in two hours (intramuscular injection), blood chemistry studies normal. X-ray studies revealed a prolapsed colon

and stomach with a probable chronic appendix.

In addition to his mental upset, therefore, he had intestinal stasis, enteroptosis and a probable mucous colitis.

The patient seemed greatly relieved when told he had no organic lesion but he was advised to enter a hospital for treatment. The effect of a complete examination with a careful explanation of the condition and reassurance had not only gained his confidence but had already started him on the road to recovery. Correction of the constipation was achieved by means of diet, enemata, etc., leading finally to bowel re-education. In addition rest, exercise and a well rounded daily routine including a requisite amount of diversion were employed and throughout, a sensible and unobtrusive psychotherapy was practiced. A rapid restoration to normal occurred.

This patient has been in communication with us by mail for a half year. He has gained weight steadily and seems to be getting along splendidly. From the tone of his letters we feel that we need not fear a "nervous breakdown" in the near future.

We must remember, as Alvarez² cautions, that "many of the people who complain bitterly of auto-intoxication symptoms are usually sensitive and keenly aware of what is going on in their bodies. It is this sensitiveness which distinguishes them from those who can go for a week quite unconscious of the fact that their bowels are crammed with feces." In addition all of us recognize the fact that "sensory impulses from the digestive tract can profoundly influence our emotions, our mental processes and our vasomotor balance." We recall the young woman who, although symptomless, was extremely frightened because she ordinarily had a bowel movement every five days and at the time of her visit to our clinic had not had a stool for eleven days. Her fears were allayed

after a thorough study and a corresponding effect was soon noticed on bowel function

There is a group of patients who are so ill-informed about their illnesses that one feels it necessary to instruct them to some extent concerning the mechanics of the digestive tract. This is certainly a hazardous business but in our experience one of two procedures may be followed — either give a thorough explanation of the condition or have it understood that the patient's ideas of the disease are erroneous and that its treatment is to be entrusted entirely to the physician in charge.

In the case of R. G. (*Case IV*), female, aged 44, the complaint was referred to the stomach. She was found to have mucous colitis. It was explained that the examinations disclosed no organic disease but she could not be convinced that her symptoms could be due to a non-organic condition. She objected to our assumption that she was a very nervous woman. It was decided to study the case in the usual psychiatric fashion but recovery was slow, tedious and never quite satisfactory. This is to be compared with H. R. S. (*Case V*), female, aged 33, in whom the same situation was met. In this case no explanations were given but various forms of medicinal therapy in addition to diet and rest were employed. At each visit, we suggested that she was certainly much better as revealed by our examinations. Drugs, never given at random, were changed to relieve gas, spasm, intestinal stasis, etc. With this form of therapy, she was brought back to usefulness in a short time. These are examples of a large group of cases which we have observed and in our experience, the latter form of treatment is much more satisfactory not only as to its immediate effect but also as to the permanency of cure.

In *Case VI*, D. V. D., a very nervous ung woman of 34 years with many

vague digestive symptoms, the instructions given were briefly as follows: "Conditions of this type necessarily involve the nervous system and it is important in considering your case to recognize this factor. Any treatment, therefore, which is undertaken, should be directed not only to the digestive tract but equally as well to the nervous system. I should therefore advise you to continue with the dietetic regime (spastic colitis), which I have given you, get considerable rest, wear your abdominal support (enteroptosis with symptoms) and get a reasonable amount of exercise. Your surroundings should be bright and cheerful and you should try as far as possible to overcome all irritations. For the constipation mineral oil is useful. A nerve tonic is advisable and the administration of hydrochloric acid (achlorhydria) with pepsin is also very helpful. I know that you will do well and I shall be very glad to cooperate with you in any way I can to help you regain your health." This, with its implied suggestions, later to be gradually amplified, serves as a basis by means of which the patient acquires the method of studying her personality.

Case VII B. M., female, aged 41 had always complained of gastro-intestinal difficulties. She had run the gauntlet of medical and surgical treatments. A complete study led to the belief that we were dealing with an unhappily married, pronounced hypochondriac whose greatest desire was to remain a chronic invalid. In cases of this type a complete psychiatric study is indicated and we therefore referred this patient to a competent psychiatrist who finally informed us that the patient would not cooperate with him and had decided to get another doctor. This type of individual often does not respond to any type of treatment and sometimes becomes institutional material. Another problem presented itself in the case of S. H. W., *Case VIII*, who had, in addition to a penetrating ulcer at the pylorus, a depressive psychosis which demanded institutional care. Here psychiatric and gastro-enterologic cooperation was necessary.

Case IX L. S., female, aged 20, complained of heartburn and a feeling of full-

ness in the epigastrium. A complete work-up led to the following impressions — Aerophagia, enteroptosis, spastic colitis, intestinal stasis, and "neurasthenia." The patient was so emotionally upset that she was hospitalized since we felt that she could not, despite every effort, modify her mental state in her present environment. Subsequent studies revealed the fact that the patient's instability was due to a shock occasioned by the death of a very dear friend. To this she reacted with what she recognized as a gastro-intestinal upset. Her treatment consisted of reassurance, diet, rest and medicinal therapy (to relieve "heartburn" and "gas formation"). She gradually recovered and it was only after she was rid of her belching and constipation that the probable association with her friend's death was discussed. She reacted admirably.

Case X W R, male, aged 33, complained of "stomach trouble" with vague abdominal discomfort which he believed was due to his "nerves." After a thorough study he was told that he was organically sound and that he had what was called "nervous indigestion." It was explained that strict adherence to a prescribed regime and his complete cooperation would doubtless rid him of his difficulty. He responded well and when last seen it was clear that he recognized the mechanism of his gastrointestinal upset.

Case XI G S, male, aged 27, presented a similar picture complicated by a subacute appendix. He feared an operation but after a week's observation, during which time the signs in his right lower quadrant remained quite definite, he submitted at our advice. Pre-operative and post-operative care were made to include sufficient analgesic preparations so that he would be spared the least pain. (He seemed to be mentally hyperesthetic.) Today, three months after operation, he is getting along splendidly and remarks that his fear of pain has disappeared.

Case XII E I F, male, aged 44, entered our clinic with many gastro-intestinal complaints which appeared when his home physician, during a periodic health examination, mentioned the necessity for ruling out cancer in certain cases. This suggestion was sufficient to set up a cancer

phobia in this individual and unconsciously he reacted with the production of numerous gastro-intestinal symptoms. The examination by us disclosed a spastic colon which responded to antispasmodic therapy. Recovery, finally, was complete, when unsolicited he was told emphatically that he 'absolutely had no cancer.'

Although emphatic reassurance is the coup d'état, straggling symptoms must be treated since their persistence may cause some patients to doubt the physician's diagnosis even though they have utmost confidence in him. An instance of the latter is the *Case XIII*, M S, female, aged 52 who was told by her physician that although her symptoms suggested gall bladder disease examination seemed to indicate a normal organ. Her symptoms persisted, however, and she visited an esteemed clinic where she was informed that only immediate cholecystectomy would afford her relief. This frightened her greatly. Several months later the patient visited our clinic where she was found to be extremely apprehensive and to have a definite mild cholecystitis. She was reassured and when her organic disease responded readily to the method of non-surgical biliary drainages of Lyon her apprehensiveness vanished.

Finally, *Case VII*, is outlined briefly because it teaches so valuable a lesson. W K, female, aged 42, is an example of that group of patients who talk incessantly of their symptoms and who unfortunately are immediately stamped as neurotics. As a matter of fact, careful examination often discloses an organic illness. W K had passed from one physician to another and in each instance was labeled "essentially neurotic." She was found to have a malignancy which later caused her death. This case impresses us with the importance of divorcing ourselves from preconceived notions. Each patient demands and deserves a thorough examination.

SUMMARY

To summarize briefly we have attempted in this paper to stress several important points two of which we should like to reiterate. The first the

necessity of a thorough survey of the patient, is generally accepted, if not practiced. The second, the use of drugs in psychoneurotics, is neither generally understood nor accepted. We have tried to show that there need be no taboo on drugs used with reason, that they are very helpful and that they are often of more psychotherapeutic value than other more frequently employed measures. In our study, we have seen a varied assortment of reaction types derive striking benefit from the temporary and rational use of drugs to relieve symptoms. We have refrained from making any statistical report at present because investigations of this nature do not easily lend themselves to mathematical arrangements. At present we simply bring forth the fact that in a large series of cases with more or less "nervous" etiologic factors the results obtained are better when a practical psychotherapy includes in addition to the usual measures (reassurance, superficial analysis, physiotherapy, rest, massage, exercise, occupational therapy) the use of drugs to relieve symptoms. If drugs are used sensibly we need not fear that they suggest organic disease and thus give the patient a reason for complain-

ing. However, we realize that this method is not applicable to all reaction-types. That there is a large group of cases where the mechanism of the reaction must be explained is agreed. On the other hand, it is a well recognized fact that the mental effect of a complete examination with an explanation of the condition and reassurance results in a "cure" in a large number of cases. As Lyon¹⁰ has aptly stated "By improving our methods of total diagnosis of a patient we thereby improve our chances of appropriately treating that patient from many angles instead of his chief major disease alone. The thoroughness of the total treatment is often the real secret of success."

We have introduced the term gastro-psychiatrist. The temperamental fitness of this individual differs greatly from the average psychiatrist or gastro-enterologist. He stresses neither the "whole" of the former, nor the "part" of the latter. He takes both into consideration *equally* and does not hesitate to cure the part while treating the whole. Not every gastro-enterologist and psychiatrist is suited for this specialty, they may practice it but not with all the attainable success.

The Prestige of the Internist*

By MILES J BREUER, M D , F A C P , *Lincoln, Nebraska*

INTERNISTS who are working in well-developed medical centers, on a basis either of referred work or of institutional work, are not frequently confronted with problems like the cases mentioned below. But from seventy-five to ninety per cent of the internal medicine of this country that is waiting and crying to be done conscientiously and scientifically, exists and awaits among the masses who do not have access to modern medical centers, whose medical conceptions are from fifteen to fifty years behind the forefront of modern medical thought, and who do not even know what an internist is. They do not understand the character of service involved in an "examination" as an internist means the word, have no idea of what a diagnostic study consists or what it can do for them. They just want a doctor. They came directly to the internist, and he must educate them to evaluate his services, or to be referred to other specialists.

Case 1, J H, aged 55, traveling salesman, called the writer into his home on a number of occasions for the relief of acute abdominal pain. The principal therapeutic measure to which the pain responded was rest. On several occasions I advised this man that there was a possibility of the existence of a circulatory lesion not apparent to the type of examination that was possible

on an emergency visit, warned him of the danger that might result from its neglect and urged him to have a proper diagnostic study. He agreed with this, until it occurred to him to ask what the cost would be. When told of the probable cost of the necessary study and observation, he backed away in dismay. On several occasions he was willing to go to a hospital and be operated on, at a cost of from four to six times as much as the diagnosis would have cost, it took some rather firm dissuasion to convince him that he did not have a surgical lesion. After he found what the proposed examination might cost, he was very resentful and did not call me any more. One day he was found dead in his car, and the autopsy showed coronary stenosis.

Case 2 was seen in connection with visit to a colleague in a neighboring city. A thin, pale young woman came to him requesting some medicine for her kidneys because of a backache. He explained to her the need of a thorough diagnostic study in a case like hers, and was also met with the question of the probable cost of such a study. The lady did not return to him, but we happened to see her about a week later when she was brought into a hospital clinic, paralyzed and anesthetic from the waist down and with sphincters paralyzed. She had gone to a chiropractor and paid him in advance for a series of treatments a sum not substantially different from the one estimated by the internist as the approximate cost of an examination. Further examination showed that she had tuberculous caries of a vertebra with fracture and compression of the cord.

As a multiplication of cases like the above could demonstrate the American public is not yet conscious of the

*Received for publication March 2 1931

internist as a new and different figure in medicine, who, on the one hand has a distinct type of service to offer differing considerably from "just going to a doctor and getting some medicine", and on the other hand who works under such conditions that there is a standard of expense connected with his services which also differs markedly from just "going to a doctor"

This lack of appreciation of the internist's function is not limited to the lay public. Just recently I received a friendly visit at my office from a man who ranks high on the surgical staffs of two hospitals and who has made a name for himself in a special field of surgery. I was showing him the records of a certain case, which at first had been diagnostically obscure, and afterwards had proved interesting enough to merit a thorough clinical study. He waved away my pile of records. "What do you want to do all of that for?" he asked in perfectly sincere deprecation, "Why don't you come right to the point?" His attitude is typically illustrative of that which I have found on the part of many medical men in our community which has the reputation of being a progressive one.

The writer does not believe in emphasizing the economic or business side of medical practice, and does not wish this article to be construed as a plea for some plan of bringing up the fees of internists. It is rather the expression of a desire to suggest the need of educating the public to understand the function of the internist, for the sole purpose of enabling the internist to function prop-

erly, and for no one's ultimate greater benefit than that of the public itself.

In this community, which is quite like ninety per cent of the rest of the United States, dentists and surgeons have already educated the public to a proper evaluation of their function, and to an acceptance of their standards of remuneration. The average man admits that the surgeon is perfectly justified in receiving a minimum of \$100 to \$300 for an operation. But, if someone should tell this same average man that the internist exercises quite as much skill and ability, assumes quite as much responsibility and that his services are of quite as much importance and value to the patient as in the case of the surgeon, he would be dubious and skeptical. He does not know enough about what an internist does, to form an intelligent opinion. And therefore, when an internist charges him a fee on a basis analogous to that of the surgeon or the dentist he is indignant and thinks he is being unjustly treated.

The reason for this is twofold. On the one hand the surgeon and the dentist have educated the public. Time and custom have succeeded in producing a willing acceptance of the situation. The public is reconciled to the cost and believes in the value of the service, and the surgeon and the dentist continue to develop their knowledge and their technic on a reasonably remunerative basis. On the other hand, there is a popular appeal about the accomplishments of surgery that is lacking in the humdrum, plodding procedures of internal medicine.

The public has a very poor knowledge and appreciation at the present time of some of the remarkable things that are being accomplished by internal medicine. Only a limited number of lay individuals are aware of the diagnostic marvels that our specialty has produced and of the therapeutic miracles that it is working. If the dissemination of such knowledge is left to the usual natural processes, it will be twenty years before the importance of electrocardiography and the magic of insulin are as much of a byword in the home as is appendectomy. Nor does the general public have any idea of the overhead expense involved in the diagnostic and therapeutic methods connected with internal medicine. Omitting entirely the consideration of the time and expense required on the part of the internist to acquire the necessary ability, what average layman has any idea of the overhead factors entering into the study of, for instance, a case with chronic epigastric pains and a loss of physical capacity, of the time and expenditure of lawyer-like skill necessary to extract the indispensable history, of the expenditures for laboratory work, the basal metabolic rate, the electrocardiogram, the x-ray, and the assistance of skilled technicians? The bill for a study of this sort stirs up the common man's resentment, because he cannot see what he has gotten for his money. Nothing illustrates this point better than the requests of many of these patients that they might keep their x-ray films, a desperate attempt to salvage something concrete and ob-

jective as a symbol of what they get for the money they have paid out.

This attitude, of course, makes the work of an internist difficult. Naturally, in response to it he makes some concessions. Either he omits work that ought to be done, or he does without charge work for which he ought to be paid. Either course handicaps the freedom of his scientific activities, unless he is fortunate enough to be practicing among a wealthy clientele, and this article is being written about the seventy-five or ninety per cent of internists and near-internists who are not so situated. From the very beginning of the study of such a case the internist feels under constraint, he knows that a financial argument is coming, and the thought interferes with the proper freedom of his efforts. It is not a question of whether or not the internist makes money. It is a question of providing him with the opportunity to study his cases adequately under a condition of affairs where the work must pay for itself. Under the present social organization most of our internal medicine is being done by men or groups who are not endowed and have no independent source of income. If the patient does not pay for the work, in the total summing up it cannot be done. Yet in all conscience it ought to be done. Therefore, the work must command adequate fees.

There is no other solution of the question than the education of the public, since most of us admit that the socialization of medical practice is a vague conception and far away from

us just now The public must be trained to recognize that an "examination" or a diagnostic study is quite as concrete and valuable a service as a surgical operation, in many cases comparably difficult and expensive

How can the public be educated?

First by that constant educational work that is being done by the individual practitioner, in personal contact with his patients After all, the doctor is today more of a teacher than a medicine man, and of no type of practitioner is this more true than of the internist

Secondly, writers from among our ranks should present the matter properly to the public through the common literary channels The procedures and accomplishments of internal medicine, the importance and difficulty of modern diagnosis, should be discussed for the popular medical reader The writer of this paper has been doing his best in that direction in the limited sphere in which his writings appear

Thirdly, the organized efforts of internal medicine should be consciously directed at the problem Every convention at which internists

gather ought to organize one meeting of its period which is open to the public for the adequate presentation of these matters to laymen

Beyond the application of the methods of modern efficiency to essential phases, the writer does not believe in any propaganda to build up the business side of our profession But, as long as the work of the internist must be self-supporting, nothing but the efficient application of modern methods of thorough and complete diagnostic study to all cases that require it, is going to meet the ideal of an adequate service to the public on our part Only a relatively small proportion of the cases that need this service, is getting it today Internal medicine is not as yet properly organized to deliver it as surgery is being delivered Yet, without modern diagnostic study of difficult and obscure conditions with a view to relief, and without the efficient recognition of early stages of serious diseases with a view to prevention, we are back in the dark ages of medical practice, and are failing to bring to the public the full benefit of modern scientific medical progress

Editorial

ON THE "CAUSE" OF CANCER

There is no dictum of medical import more commonly in the mouth of the layman than that the 'cause' of cancer is unknown. Lawyers make unfair use of it in compensation cases and the presiding judicial officer falls readily into the same trap. The medical witness is asked if he knows the cause of cancer and he modestly replies in the negative. He is then asked if *anyone* knows the cause of cancer and the usual answer is that as far as he knows the cause of cancer is not known. The questioner then makes his point by asking if, since the cause of cancer is not known, it is not just as probable in the case in question that cancer was due to such and such a factor as to anything else, and the witness gives a feeble and unwilling assent, although his best judgment tells him that it was highly improbable that any causal relationship existed.

The difficulty lies in the form of the question itself. The cause of disease is always complex. It does not tell the whole truth to say that the cause of tuberculosis is the tubercle bacillus. Not only does the more immediate physical and humoral constitution of the host determine whether the disease is to develop, but the entire phylogenetic experience of the two interacting organisms lies back of that form of abnormal life and abnormal living that constitutes tuberculosis. Innumerable

homely examples of the difficulty inherent in the form of the question can be found in everyday life. It is as though one had asked the cause of an elephant. In answer to such a query the keeper might think of the supply of provender which had been consumed during the long years of growth from birth to maturity, the geneticist of the union of the male and female reproductive cells with their intricate apparatus for the transmissal of unit characters, and the evolutionist of the millions of years of trial and error and success which have given to the elephant the huge bulk, thick skin, prehensile trunk and large ears which are part of his successful adjustment to his native habitat. But back of all this, and yet a part of it, as the chief cause of all, is life itself. It is equally true that life is a cause of cancer for the problems of neoplasia are the problems of *living* tumor cells descended from *living* body cells. Thus the question as to the cause of cancer is difficult and in a sense impossible to answer because its simplicity makes it profound.

Much is known, however, about factors which are concerned with the development of cancer and in one sense it may be said that the cause is known for the experimental pathologist can produce cancer at will. In suitable species of laboratory animals malignant neoplasms may be made to arise

de novo The lines along which this success has been attained point the way toward a classification of the known carcinogenic factors in man. On the one hand carcinoma can be produced in suitable laboratory animals by selective breeding, and on the other by the application of various extrinsic agents, as exemplified by the historical induction of carcinoma of the stomach of the rat by Fibiger through feeding cockroaches containing a nematode worm (*Spinoptera neoplastica*), and of the ear of the rabbit by painting with tar (*Yamagita*), brilliant successes of the greatest significance which in more recent years have been paralleled by various other workers using several diverse procedures. Thus the known factors productive of neoplasms fall into two main groups, one containing those which are inherent or developmental, and therefore peculiar to the individual, and the other made up of the *extrinsic* agents. The first of these groups has in turn two aspects. It must be divided into those factors which are disturbances of development in the morphological sense, *embryonal*, and those which are inherent in the genetic complexion of the individual, *intrinsic*. Thus it will be seen that the embryonal factors are developmental, the intrinsic factors are inheritable and the extrinsic factors are environmental.

The conception of an *embryonal* factor in the causation of neoplasms is of long standing (Cohnheim) and the list of tumors dependent in one way or another upon developmental defects such as the misplacement of simple or complex tissues, inclusion of tissue elements or even detached blastomeres

(included twins), and the persistence of embryonic structures into post-fetal life, is constantly increasing. Many varieties of new growths, both benign and malignant, have their origin upon such a basis. The teratomas of testis and ovary, hypernephroma, adamantinoma, chordoma, the mixed salivary gland tumors and many others thus arise. Yet it is equally true that many of the most common forms of carcinoma such as those of the lip, gastrointestinal tract and uterus cannot be thus explained.

The *intrinsic* factor stands in the forefront in the minds of many investigators today. Two great lines of evidence have supported it, the study of human inheritance as shown by certain so-called 'cancer families' (recently discussed in the ANNALS*), and the results of animal breeding experiments (Slye, Little, Lynch and others). The geneticists may differ among themselves as to the mendelian implication and interpretation of their results but there can be no doubt that under the conditions of the experimental laboratory the predisposition to the development of neoplasms can be bred in or out at the will of the trained investigator. Nor should it be expected that precise mendelian ratios will appear in such experimental series for the intrinsic factor is apparently a predisposing one only and the simultaneous operation of other factors must not be forgotten. There is some reason for believing that the intrinsic factor may be inherited in varying degrees of intensity.

*WARTHIN, A. S. Heredity of carcinoma in man. Ann Int Med, 1931, 11, 681-696.

That many *extrinsic* factors are carcinogenic has long been recognized. Chimney sweeps' cancer of the scrotum, the kangri cancer of the shepherds of Tibet, the more recently recognized mule spinners' cancer and, within our own profession, the many examples of carcinoma of hands and face among the earlier roentgenologists have provided ample proof. These are but a few of the many occupational, accidental and experimental examples of the effect of such extrinsic agents. Mechanical, thermal, chemical and radio-active forces are all found in the list. Here, also, are examples of chronic infection providing the instigating factor, but only through such mechanisms as chronic irritation and exaggerated response to injury does infection cause cancer. There is almost complete agreement among investigators that there cannot be a specific extrinsic living organism, infection with which causes cancer. There are important theoretical objections to such an etiology that cannot be entered into here. It is significant that there is no proved example of the transfer of a neoplasm from patient to nurse, doctor, or to any member of the patient's family. But chronic inflammation due to infection, with excessive reparative proliferation such as may be associated with lupus, or at the mouth of a sinus or the border of an ulcer, may provide the extrinsic stimulus. It is from the field of occupational medicine that much of our knowledge of extrinsic carcinogenic factors has come. The list includes soot tar, pitch, creosote, shale oil, petroleum, arsenic, aniline dyes, anthracene, radium, roentgen-rays, sunlight, burns

of thermal, electrical and chemical origin, and repeated mechanical trauma.

The relative potency and the mode of interaction of the developmental, the intrinsic and the extrinsic factors we know relatively little about, although evidence of value in this respect is accumulating. For purposes of illustration and discussion a mathematical form is of use. If D represents the developmental (embryonic) factor, E the extrinsic factor and I the intrinsic factor, the following equations should be true:

$$(I) \quad I + D + E = \text{cancer},$$

$$(II) \quad I + E = \text{cancer},$$

$$(III) \quad I + D = \text{cancer}$$

Since both human family histories and animal breeding experiments include strains in which practically every individual succumbs to a malignant neoplasm it seems highly probable that if the intrinsic predisposition is of a certain degree of intensity or combined with a certain organ predisposition either no extrinsic factor is needed or the ordinary minor environmental traumata may assume that role. The origin of cancer in such a case may be expressed by the equation:

$$(IV) \quad I = \text{cancer}$$

It is not so clear whether or not cancer can ever develop in the absence of the intrinsic factor. That certain pioneer roentgenologists daily and many times a day placed their hands before the fluoroscope to test the efficiency of their tubes and never developed cancer in spite of such protracted and intensive exposure may be due to the fact that they lacked the intrinsic predisposition.

If so the equation

$$(V) \quad I = \text{no cancer}$$

should be accepted as true. It might be a fruitful research to compare the family histories of the x-ray workers who developed cancer with the family histories of those who did not. If the intrinsic factor is necessary under such circumstances, may it not be true also, that

(VI) $D = \text{no cancer}$,
and (VII) $D + E = \text{no cancer?}$

Of this there is, as yet, no proof.

A brief survey of present opinion of the cause of cancer indicates that, after

all, much has been accomplished and much is known. Members of the medical profession will do well to present such material to intelligent laymen and thus aid in dispelling the popular opinion that cancer research has reached an *impasse*. As Woglom put it not long ago, one need only ask a medical man whether he would rather have a carcinoma now, or thirty years ago, to learn whether there has been any progress in our knowledge of the cause, prevention, diagnosis and treatment of cancer during that period.

Abstracts

Blood Cultures and Focal Infections An Experimental Study with One Hundred Healthy Adults By GORDON C CAMERON, C A RAE and GEO N MURPHY (Canadian Med Assoc Jr, 1931, xxv, 131-134)

Although it is generally assumed that the blood-stream of the healthy animal is normally free of bacteria there is much evidence, however, to indicate that pathogenic organisms do invade the blood-stream without necessarily producing disease. This is indicated by the frequent development of staphylococcic osteomyelitis following forms of trauma which could not effect the introduction of organisms. The subjects used in this investigation were presumably healthy young men who were interrogated as to present health and previous experience with disease. Inspection of the nose, throat and ears of each was carried out, as well as a detailed examination of the teeth with complete x-rays. A 20 cc sample of blood from each subject was incubated with 180 cc of beef heart infusion broth. These cultures were examined daily but were opened only after two weeks and four weeks of incubation. Of the 100 cultures, 81 remained without growth. Among the 19 showing growth it seemed certain that 12, and possibly 13, were contaminated. The remaining 6 showed growth of organisms believed to be derived from the blood. Four of these were characteristic of *Staphylococcus aureus* and the other two were "diphtheroids". Although there were 25 individuals in the group with x-ray evidence of apical disease of from one to four teeth, not one of the six positive cultures came from this group. One of the subjects who yielded a culture of *S. aureus* had a mucopurulent discharge from the right nostril, partial right nasal obstruction, a dim right antrum, enlarged tonsils and enlarged cervical nodes. The others were free of abnormalities which might be interpreted as disease except that two had a pustular acne on the back. While

aware that the method used might fail to demonstrate certain of the more dependent parasitic organisms, it was chosen in order to permit speed and simplicity in manipulation.

Metastatic Tumors in the Thyroid Gland By RUPERT A WILLIS (The Am Jr of Path, 1931, vii, 187-208)

In cases of systemic hematogenous dissemination of malignant tumors, the embolic influx into the various tissues must be proportional to their respective arterial blood supplies, yet such richly vascular organs as the intestine, spleen and thyroid gland are relatively infrequent sites for secondary growths resulting from hematogenous spread. Taking the total weights of the liver and thyroid to be 1500 and 25 grams respectively, it appears that the thyroid actually receives about one-half the volume of arterial blood received by the entire liver. Yet, while the liver is very frequently the seat of metastases derived from the systemic blood stream metastatic growths in the thyroid gland are unusual. The author collected and reviewed the records of 47 examples of metastatic thyroid growths, and added 10 cases personally observed. He concluded that secondary tumors occur more frequently in the thyroid than they are generally recognized partly due to failure to make thorough examination of this organ in doing autopsies upon the bodies of those dying of malignant disease. There are good grounds for believing that different tumor types possess different intrinsic capacities for establishing metastases in the thyroid and that melanomas and lung carcinomas are most potent in this respect. There is strong evidence that areas of abnormal thyroid tissue such as adenomas are predisposed to the establishment of metastatic neoplasms and that this predisposition depends on chemical or metabolic rather than on vascular changes in the altered tissues.

This predisposition on the part of pre-existing abnormal areas appears especially in connection with the metastases of neoplasms having relatively little tendency to colonize in the thyroid gland

The Blood Sugar of Normal Fasting Persons By B Y GLASSBERG (Proc Soc Exp Biol and Med, 1931, xxviii, 889-893)

The blood sugar values recorded generally in the literature represent the sum of the sugar and non-sugar reducing substances present. Somogyi has perfected a simple method of precipitation with zinc salts whereby, together with the blood proteins, the reducing non-sugars also are precipitated and thus filtrates are obtained that contain no appreciable amount of reducing substances other than sugar. Using such zinc filtrates, true sugar values are obtained in a single determination by any of the titrimetric or colorimetric methods in general use. The author determined the fasting true blood sugar in 100 normal adults, 50 men and 50 women. Samples were taken before breakfast, at least eight hours after the last meal. Somogyi's microtechnique for zinc precipitation combined with the Shaffer-Hartmann method was employed. Blood was obtained by puncture of the finger tip, the hand having been previously warmed in a basin of warm water. It was determined that capillary blood may properly be substituted for venous blood in determining the sugar of fasting individuals and that repeated squeezing of the finger to obtain successive samples did not modify the result through the admixture of other tissue fluids. The fasting true blood sugar of 50 men and 50 women was found to be between 70 and 95 mg per 100 cc of blood, with an average of 81.6 mg. The lowest blood sugar obtained was 70 mg, the highest 95.

Case of Pneumococcus (Type III) Meningitis Treated with Potassium Permanganate—Recovery By MAX H WEINBERG

(Jr Nerv and Mental Dis, 1931, lxxiv, 38-45)

The very serious if not hopeless prognosis in pneumococcus meningitis has justified the use of various drastic methods of treatment such as continuous drainage, cisterna magna punctures, lavage of the ventricles and the injection of various irritating substances into the subarachnoid space. Stimulated by the results obtained by Chester in the treatment of pneumonia, as reported in the ANNALS in 1929, the author used potassium permanganate enemata in a case of meningitis shown bacteriologically to be due to pneumococcus, type III. A cleansing enema is first given followed by 4 ounces of the standard solution advocated by Nott, which contains 2 grains of potassium permanganate to one and one-half pints of water. Such enemata were given every four hours. The patient should lie on his left side and remain so for at least twenty minutes to facilitate retention. In the case described the patient made a rapid recovery and was practically normal eleven days after instituting treatment.

Suppression of Strychnine Convulsions by Barbiturates By W T DAWSON and CHARLES H TART, Jr (Proc Soc Exp Biol and Med, 1931, xxviii, 917-918)

Barbital (diethyl barbituric acid), phenobarbital (ethyl-phenyl), nembutal (ethyl-secondary amyl) and pernocton (B-bromallyl secondary butyl) were all found to possess the life-saving antagonistic action to strychnine poisoning which Zerkas and McCallum demonstrated for amytal (ethylisomyl barbituric acid). By starting the administration of these drugs with the onset of convulsions it was found possible to save the lives of rabbits which had received strychnine in an amount in excess of the certain lethal dose. Phenobarbital was much more effective than barbital when judged by the amount of the drug necessary to control convulsions.

Reviews

Sixty Centuries of Health and Physick The Progress of Ideas from Primitive Magic to Modern Medicine By S G BLAXLAND STUBBS and E W BLIGH With an Introduction by Sir HUMPHREY ROLLESTON xvi + 253 pages, 64 plates Paul B Hoeber, Inc., New York City, 1931 Price, \$5.00

As Sir Humphrey Rolleston puts it in his introduction to this book, what embryology is to the study of man's structure and evolution, history is to the comprehension of an art or science. Thus it is easy to understand why the study of the History of Medicine has recently attracted more and more attention both in and outside the ranks of the medical profession. The present work, however, is by no means a history of Medicine in the usual sense. Rather it is an account of the growth and progress, the evolution of ideas, having to do with the search for health and its preservation. The preventive idea thus receives special emphasis throughout. While of necessity certain names and dates must appear, the pages are not made to bristle with them and the reader cannot lose sight of the progress of the central theme as the way is marked from primitive medicine to Metchnikoff, Banting and Theobald Adrian Palm, oftentimes by quotations from original sources. The illustrations are very well reproduced as full-page plates and add much to the value of the book. While written for the layman with an interest in the development of medical science, it should make an equally strong appeal to the medical man himself. Here is a book which the doctor can recommend to his lay friends as giving an interesting account of the development of modern preventive Medicine. We quote from the final paragraph: "It is often said that the future of Medicine is in the laboratory. Doubtless this is true, but it is through the agency of the devoted and observant practitioner that Health comes with healing in her

wings. The problem will be to convey the knowledge gained in the laboratory to the one man who can put it to practical use.

The Doctor and His Investments Financial Policy and Technique for the Physician By MERRYLE STANLEY RUCKEYER, B. Lit. M. A., Financial Editor, Medical Economics and Dental Survey, Financial and Editorial Writer, New York American and Associated Newspapers, Associate in Journalism, Columbia University ix + 330 pages P. Blakiston's Son and Company Philadelphia, 1931 Price \$2.50 postpaid

The doctor is faced with investment problems quite unlike those of the average business man. He cannot provide for the future by turning his profits back into his business. Even if he practices this by improving himself through graduate study and travel that investment dies with him in fact becomes useless when his active work ceases. The doctor must invest as a method of self-pensioning as well as for the purpose of providing for his family. Physicians as a class are readily susceptible to the suggestions of insincere advisers and doctors' names figure largely on the sucker lists of security charlatans. Well-meaning acquaintances and grateful patients find the doctor a childlike and trustful listener to amateurish financial advice although he would be the last to select a medical consultant by that method. The book under review considers with sympathy and understanding the financial problems peculiar to the physician. The twenty-seven chapters are grouped in three parts dealing respectively with the Investment Policy for Doctors, Fields of Investment for Doctors and Fitting Investments to the Doctor's Needs. Throughout a thorough knowledge of medical economics is revealed particularly in such chapters as those which deal with equipping the doctor's office with the pros and cons of Medical Arts Publishing and

with financial set-ups ensuring a proper perpetuation of clinical groups. A suitable life-term plan, an annual financial health examination, a proper diversification and a healthy conservatism are subjects receiving emphasis. Finally, definite financial prescriptions are offered for concrete cases covering the needs of the bachelor physician, the doctor with a family and the retiring medical man. This book deserves the fullest commendation. It can render a valuable service to all members of the profession.

Practical Dietetics for Adults and Children in Health and Disease By SANFORD BLUM, A B, M S, M D, Head of Department of Pediatrics and Director of the Research Laboratory, San Francisco Polyclinic and Post Graduate School. Fourth revised and enlarged edition. xi + 380 pages. F. A. Davis Company, Philadelphia, 1931. Price, \$4.00 net.

This, the fourth edition of this work, differs from the preceding chiefly in the addition of a list of the chief sources of vitamins and a discussion of alkaline foods and diets. Detailed dietaries are given for healthy individuals of various types and conditions, as well as for those suffering from a variety of diseases. This book must prove of considerable use to the physician who is frequently called upon to give concrete advice, rather than broad suggestions, in dietary matters. The reader may grope, as does the reviewer, to learn why a spinster with impaired digestion is permitted to eat cauliflower but forbidden to eat cabbage (provided the mode of cooking is the same), or what difference in dietary value causes tongue muscle to be taboo for those who are encouraged to eat steaks, roast beef and roast mutton.

A Manual of the Common Contagious Diseases By PHILIP MOEN STIMSON, A B, M D, Associate in Pediatrics, Cornell University Medical College, Attending Physician, Willard Parker Hospital, Chief of Staff, the Floating Hospital of St. John's Guild, Chief of Clinic, Department

of Pediatrics, Cornell Clinic, etc. xvi + 353 pages, 2 plates and 40 text figures. Lea and Febiger, Philadelphia, 1931. Price, limp binding, \$3.75, net.

This manual was intended primarily as a clinical guide for medical students and internes but also includes the practical working directions needed by the nurse in charge of a patient with a contagious disease. It should be of great value to all practitioners and particularly to school physicians. Concisely written, it is also surprisingly complete. The diseases considered are diphtheria, Vincent's angina, scarlet fever, measles, rubella, whooping cough, mumps, chicken pox, vaccinia, epidemic meningitis and poliomyelitis. In addition there are chapters on the principles of contagion, serum reactions and the general management of contagious diseases. The size of the book is convenient and the binding durable and practical. This manual can be heartily recommended to those desiring a concise reference text on the common contagious diseases and their management.

Chronic Arthritis and Rheumatoid Affections with Recovery Record By BERNARD LANGDON WYATT, M D, F A C P, with the collaboration of LOUIS I. DUBLIN and foreword by DOCTOR J. VAN BREEMAN. ix + 166 pages. William Wood and Company, New York, 1930. Price, \$2.50.

A chapter on the incidence of rheumatic disease is followed by one on types and causes, the two occupying 34 pages. Preventive measures and early diagnosis account for the next 22 pages. The remainder of this book deals with therapeutic procedures, particularly diet and physical agencies. Herein lies its value, for specific suggestions free from narrow prejudices are to be found. The author is fully alive to the futility of dietary fads, and the question of focal infection is treated with commendable restraint. At the end a number of blanks are provided upon which the patient may record progress notes, this procedure having been found to be of considerable value in securing his intelligent cooperation.

College News Notes

At the recent meeting of the American Society of Clinical Pathologists in Philadelphia, Dr Walter M Simpson (Fellow), Dayton, Ohio, was chosen as President-Elect of the Society

Dr Austin B Jones (Fellow), Kansas City, Mo, was elected President of the Internist Club during the May meeting

A Dermatologic Clinic on "Erythema Induratum", held by Dr Ralph Bernstein (Fellow), Professor of Dermatology, Hahnemann Medical College of Philadelphia, was published in the July number of the Hahnemannian Monthly

Dr Harold L Amoss (Fellow), Durham, N C, has gone to Peiping, China, for a four months' stay, as Visiting Professor in the Peiping Union Medical College

At the meeting of the 6th District Medical Society of the State of North Carolina, held in Durham on June 18, Dr Robert L Felts (Fellow), of Durham, was elected President for the ensuing year

Dr Thurman D Kitchin (Fellow), Wake Forest, N C, President of Wake Forest College and Dean of the Medical School of Wake Forest College, was recently appointed to serve on the Commission for the Improvement of the Laws of North Carolina, provided by the last General Assembly

Dr Verne S Caviness (Fellow), Raleigh, N C, read a paper on "The Early Diagnosis of Pellagra" before the North Carolina State Medical Society's meeting during April. This paper was published in the July Issue of Southern Medicine and Surgery

Dr Caviness also read a paper on "Blood Pressure" before the Johnson County (North Carolina) Medical Society on June

Dr Samuel W Sappington (Fellow), Philadelphia, is the author of an article, "Death's Time Table and Passing Remarks," which was published in the July issue of the Hahnemannian Monthly

Dr Clement C Fihe (Fellow), Cincinnati, Ohio, was one of the guest speakers at a recent meeting of the Bourbon County (Ky) Medical Society

The North Carolina Radiological Society was recently formed with the following Fellows of the College holding offices

Dr J K Pepper, Winston-Salem—President

Dr W T Ramey, Fayetteville—Vice-President

Dr Sylvester D Craig (Fellow), Winston-Salem, N C, was elected a member of the State Board of Health during the recent meeting of the North Carolina State Medical Society

Dr Thomas E Rogers (Fellow), Macon, Ga, read a paper on "Diagnosis and Treatment of Cardiac Arrhythmias" before the Sixth District Medical Society which met on June 24 at Indian Springs

Dr LaRue D Carter (Fellow) Indianapolis, addressed the Jay County (Indiana) Medical Society, July 2 on "Muscular Dystrophy"

Dr Thomas W Oberlin (Fellow) Hammond was elected President of the Indiana State Board of Health for two years during a reorganization meeting on July 2

Dr Henry G Rudner (Fellow) Memphis, Tenn, on June 18 addressed the East Mississippi Medical Society Philadelphia on "Symptoms of Colon Intoxication"

Main entrance to Duke Hospital of the Duke University School of Medicine, showing the Seal of the American College of Physicians above the door at the right and the Seal of the American College of Surgeons above the door at the left

DEDICATION OF THE
DUKE UNIVERSITY SCHOOL OF
MEDICINE
AND THE
DUKE HOSPITAL

ON
April 20, 1931

The new Duke University School of Medicine and the Duke Hospital were fittingly dedicated at Durham, N C, with an elaborate program. The erection of the School of Medicine and the Hospital marks another completed step in a far-reaching program conceived by Washington Duke and further advanced by his sons, Benjamin N and James B Duke, the latter of whom is directly responsible for the munificent gift founding the Duke University School of Medicine and the Duke Hospital in 1925. The cost of erecting the buildings for the School of Medicine and Hospital exceed four million dollars, leaving an endowment of six million dollars for maintenance. The architecture of all buildings is Gothic, there is but one architect for all the University buildings, resulting in a symmetry of design seldom carried out so fully in other American universities.

The wards in the new Duke Hospital have been named for distinguished physicians and surgeons, largely of the South, as follows: William H Welch, the only living physician for whom a ward is named, and who attended the dedication exercises, Sir William Osler, noted physician who made his home in Maryland for many years, Josiah Clark Nott, of South Carolina, Daniel Drake, of Kentucky, Walter Reed, of Virginia, William Stewart Halsted, of Maryland, Edmund Charles Fox Strudwick, of North Carolina, Crawford Williamson Long, of Georgia, Ephraim McDowell, of Kentucky, James L Cabell, of Virginia, J Marion Sims, of South Carolina, Francois Prevost, of Louisiana, and Henry Fraser Campbell, of Georgia.

Dr Wilburt C Davison (Fellow) is Dean of the Duke University School of Medicine. Other Fellows connected with the School are Dr Harold L Amoss, Professor of Medicine, Dr William DeB MacNider, Chapel

Hill, N C, Visiting Lecturer in Special Pharmacology, Dr P P McCain Sanatorium, N C, Visiting Lecturer in Medicine.

Dr John E Greiwe (Fellow), Cincinnati, gave an illustrated lecture on "The Influence of the Peripheral Circulation" before the Darke County (Ohio) Medical Society on May 8.

The 84th semi-annual joint meeting of the Miami and Shelby County (Ohio) Medical Societies was addressed on June 4 by Dr Walter M Simpson (Fellow), Dayton on "Recent Developments in Undulant Fever".

Dr Byrl R Kirklin (Fellow), Rochester, Minn, was a guest speaker during the meeting of the Norfolk County (Va) Medical Society on June 1, the subject of his paper was "Gastric and Duodenal Ulcers".

Dr Jay A Myers (Fellow), Minneapolis, addressed the Washington Tuberculosis Association at Wenatchee, June 11-13, on tuberculosis problems.

Dr John T Strawn (Fellow) Des Moines, Ia spoke on "Gastric and Duodenal Ulcers" before the Madison County (Ia), Medical Society on June 8.

Beginning August 17, Dr Carl J Wiggers (Fellow), Cleveland, Ohio, conducted a vacation course on the principles and practice of electrocardiography at Western Reserve University School of Medicine.

Dr Henry H Turner (Associate) Oklahoma City, was among the speakers at the meeting of the Southeastern Oklahoma Medical Association on June 24. The title of his paper was "Ether Anesthesia".

Dr James S McMaster (Fellow) Birmingham, Ala addressed the Chattanooga and Hamilton County (Tenn) Medical Society July 9 on "Protein Quota in Health and Disease".

Dr Ray C Blankenship (Fellow) Madison, Wis, spoke on "Colitis" before the Ma-

nette-Florence County (Wis) Medical Society on July 9

Dr George B Eusterman (Fellow), Rochester, Minn, will address the ninetyeth annual meeting of the State Medical Society of Wisconsin, September 9-11, on "Carcinomatous Gastric Lesions Masquerading as Benign Ulcer"

A portrait, the work of Thomas C Corner, of Baltimore, of Major General Merritte W Ireland (Fellow) was unveiled in connection with a farewell reception given Dr. and Mrs Ireland, May 29, at the Army Medical Center, on the occasion of his retirement as Surgeon General of the U S Army The portrait will hang in the Administrative Offices of the new building of the Army Medical School

Col Matthew A Delaney (Fellow), Fifth Corps Area, Fort Hayes, Columbus, Ohio, beginning January 1, 1932, will be Assistant to Surgeon General Robert U Patterson of the U S Army, and will be advanced to the rank of Brigadier General Col Delaney was formerly Assistant Executive in the Surgeon General's Office During the World War, he served, first, in charge of Base Hospital No 10, and later as Liaison Officer with the British War Office He was the recipient of the Distinguished Service Medal, and also was decorated by the British Government

Col Charles F Craig (Fellow), after a service of thirty-three years, at his own request, has been retired from the Medical Corps of the U S Army He has accepted the appointment as Professor of Tropical Medicine and Director of the Department of Tropical Medicine at Tulane University of Louisiana School of Medicine

Col Craig is a graduate of Yale University School of Medicine He did postgraduate work in the Bureau of Science, Manila, and in the Rockefeller Institute for Medical Research From 1910-1911, he was Assistant Professor of Bacteriology at Yale University School of Medicine, from 1909-1922, Associate Professor and Professor of Bacteriol-

ogy, the Army Medical School, from 1926 to recently, he was Professor and Director of the Department of Laboratories and Preventive Medicine at the Army Medical School During the World War, he received the Distinguished Service Medal

In addition, Col Craig served four years as Commanding Officer of the Central Department Laboratory, Fort Leavenworth, Kansas, one year in charge of the Departmental Laboratory at El Paso, Texas, and four years as Medical Inspector in Hawaii

TULANE ESTABLISHES NEW DEPARTMENT OF PREVENTIVE MEDICINE

Announcement has recently been made that Tulane University of Louisiana School of Medicine has established a new Department of Preventive Medicine in connection with "the Commonwealth Fund of New York through which the University will participate in the rural health program recently initiated in Mississippi by the fund An annual appropriation of \$25,000 has been allotted by the fund to the School of Medicine to establish the new department and to encourage attention to preventive medicine in other clinical departments Five free scholarships have been established for undergraduate medical students from Mississippi, providing the student with \$1,200 a year for four years, with the requirement that after graduation he shall practice at least three years in Mississippi In addition, fifteen practicing physicians will be sent each year to Tulane for four months' graduate work Their tuition and transportation to and from New Orleans will be paid by the fund, and they will be allowed a monthly stipend of \$250" The arrangement with Tulane is said to be similar to that made with Harvard University Medical School for practitioners of Massachusetts

Acknowledgment is made of the following gifts of reprints and books by members to the College Library

Dr Oscar W Bethea (Fellow), New Orleans, La —4 reprints

Dr Orville H Brown (Fellow), Phoenix,
Ariz —11 reprints

Dr John L Chester (Fellow), Detroit,
Mich —1 book, "Rheumatic Fever—A Heart
Disease"

Dr Edward E Cornwall (Fellow), Brook-
lyn, N Y —1 reprint

Dr Oswald E Denney (Fellow), Carville,
La —12 reprints

Dr J L Goforth (Fellow), Dallas, Texas
—10 reprints

Dr George R Herrmann (Fellow), Gal-
veston, Texas —1 bound volume containing
sixty-two reprints

Dr Thomas Hall Shastid (Fellow), Du-
luth, Minn —1 reprint

Dr William H Strietmann (Fellow)
Oakland, Calif —1 reprint

OBITUARIES

DOCTOR LEONARD NAPOLEON
BOSTON

Dr Leonard Napoleon Boston (Fellow), a widely known physician of Philadelphia, died on July 4, 1931, at the age of fifty-nine years. Born in Shickshinny, Pennsylvania, on March 18, 1872, the son of Alfred H. and Bethiah (Bacon) Boston, a daughter of Rev. Septimus Bacon, who served in the War of 1812, Dr. Boston was educated at Huntington Mills Academy, Minneapolis High School and Atchison Commercial College, Atchison, Kansas. He taught school and attended college conjointly prior to entering the Medico-Chirurgical College, from which he was graduated in 1896. In 1895 Dr. Boston was graduated from the Philadelphia School of Anatomy with highest honors, in 1902 he received the honorary degree of A.M. from Ursinus College.

Two years after taking his medical degree, Dr. Boston became the Bacteriologist to the Philadelphia General Hospital, a position he held for six years. In 1901 he was appointed Bacteriologist of the Ayer Clinical Laboratory, Pennsylvania Hospital. He was Director of Clinical Laboratories at the Medico-Chirurgical College from 1901 to 1905. In 1906 Dr. Boston was appointed Director of the Clinical Laboratories of Research of the American Hospital for Diseases of the Stomach and soon thereafter became Pathologist at the Frankford Hospital. One year previously (1905) he was married to Miss Caroline Crandall of Westerly, Rhode Island.

Whilst Dr. Boston quite early directed his attention to bacteriology and

later pathology, he at no time forsook the clinical aspects of medicine for the laboratory side. For example, from 1897 to 1899 he was Instructor in Obstetrics at the Medico-Chirurgical College, Instructor of Medicine in the same school from 1899 to 1901, Associate in Medicine in 1904 and Adjunct Professor of Medicine from 1905 until 1912 when he was elected to a newly created chair of Physical Diagnosis, this professorship he continued to hold in the Medico-Chirurgical College, Graduate School of Medicine of the University of Pennsylvania, until 1817 when he became Assistant Professor of Medicine in the latter school, holding that position until his untimely death.

At the time of his demise, Dr. Boston was Professor of Principles and Practice of Medicine and Clinical Medicine in the Woman's Medical College of Pennsylvania, this important chair he had worthily filled since 1928. For a quarter of a century he was one of the physicians to the Philadelphia General Hospital. Here he gave much of his time and energy to bedside teaching—a form of instruction in which he excelled.

Dr. Boston was an author of note. In 1904 he published a text-book on "Clinical Diagnosis by Laboratory Methods." He was co-author with the writer of a text-book of "Medical Diagnosis," which appeared in 1911, and passed through three editions. He built up his enviable and well-earned reputation as practitioner, consultant, author and teacher, by his tireless energy and native ability, as well as high ethical ideals. Doubtless, he owed

some of his success to his unfailing courage and optimism

Toward his patients, he ever manifested deep human sympathy and at all times he radiated moral qualities which endeared him to his numerous friends. At social and professional gatherings, Dr Boston was a retiring figure, although upon being engaged in conversation was both entertaining and interesting, revealing an unusual fund of general and scientific knowledge. It is to be recollected, however, that his higher qualities of excellence emanated from the heart.

Dr Boston was the author not only of text-books, but of upwards of sixty scientific papers, many of which showed his bent for original laboratory and clinical observations. He held membership in many scientific societies and clubs, among which were the College of Physicians of Philadelphia, the Philadelphia County Medical Society, Medical Society of the State of Pennsylvania, the American Medical Association, American College of Physicians, Pathological Society of Philadelphia, the Society for the Study of Allergy, the Society of the War of 1812, the Sons of the American Revolution, the University Club and the Rotary Club of Philadelphia.

After he was graduated in medicine, Dr Boston settled in Philadelphia and took up general medicine. At the same time he became the office assistant to the writer for a period of seven years. During that period he manifested remarkable industry and loyalty performing every duty with absolute fidelity. His subsequent career was characterized by assiduous activity and devotion to the many duties devolving

upon him, until interrupted by the appearance of a serious cardio-vascular condition which, during the last four months of his life, incapacitated him from professorial and other professional duties. During this closing period of his busy life, coronary occlusion, most probably due to an atheromatous condition of the root of the aorta and the coronaries developed.

Surviving him are Mrs Caroline Crandall Boston, his widow, a daughter, Miss Barbara C Boston, a sister Mrs Myrtle B Eyler, and a brother Dr C A Boston.

DOCTOR JAMES P SCHUREMAN

Dr James P Schureman (Fellow) New Brunswick, N J died May 6 1931, aged, 51 years.

Dr Schureman graduated from Princeton University in 1901, and from the University of Michigan Medical School in 1905. He was one of the most prominent physicians in Middlesex County and was the first Fellow of the American College of Physicians in this part of New Jersey. He was highly respected by his colleagues and by the citizens of New Brunswick.

Dr Schureman was a man of charming personality, unselfish, most conscientious and devoted to the interests of his family and friends as well as patients. His family has been prominent in New Brunswick for nearly two hundred years. Dr Schureman was an Attending Physician on the Staffs of St Peter's General Hospital, Middlesex General Hospital and

Parker Home He was a Fellow of the American Medical Association, a member of the New Jersey State Medical Association and of the local societies He had been a Fellow of the American College of Physicians since 1925

Although interested in civic affairs

and a Trustee of the Anable School, Dr Schureman devoted practically his entire time to his professional work (Internal Medicine) and hospital affiliations

Variations in Manifestations of Rheumatic Fever in Relation to Climate*

By WARFIELD T. LONGCOPE, M.D., F.A.C.P., *Baltimore, Md*

THE statement can frequently be found in textbooks and monographs that rheumatic fever is ubiquitous. This generalization (which is often attributed to Hirsch¹) can, however, scarcely be accepted today. Aside from the interest which has always been aroused by the seasonal incidence and familial occurrence of rheumatic fever, as well as the yearly variations in the severity of the disease there has recently been some attempt to study, more accurately than has been possible before, the geographical distribution of the disease. The matter is one of importance not only in relation to rheumatic fever but in connection with other diseases. It is now well recognized for instance that infections such as scarlet fever and diphtheria so common in the temperate zones are almost unknown in some tropical countries. The geographical distribution of pernicious anemia also, is very irregular. It is said to be almost unknown in China and Japan (Mills-)

My interest in possible climatological differences in the symptomatology

of rheumatic fever was awakened almost ten years ago on coming to Baltimore from New York. Arthritis was often the predominant symptom of acute rheumatic fever in the adult in New York and the one for which the patient called the physician or entered the hospital. Combined with the severe arthritis, or sometimes without severe arthritis, there was not infrequently observed acute severe, and sometimes fatal endocarditis, pericarditis, myocarditis, pleurisy and pneumonia.

In Baltimore on the other hand the acute severe arthritis so familiar in New York was rarely encountered in the wards of the hospital. In general though the disease seemed common in Baltimore it presented a somewhat different clinical picture appearing more insidious, less outspoken in its arthritic manifestations, not so fulminant in its severer forms but suggesting usually a chronic or relapsing progressive disease of the heart. In order to obtain more definite information on these points the case histories of patients with rheumatic fever treated during the last five years in the adult medical wards of the Johns Hopkins Hospital have been analysed.

*From the Medical Clinic, the School of Medicine, Johns Hopkins University and Hospital. Read at the Baltimore Meeting of the American College of Physicians, March 23, 1931.

It is difficult, as Newsholme³, who was interested in this question, found many years ago, to obtain accurate information regarding the regional distribution of rheumatic fever throughout the world. The statistics collected from hospitals by Faulkner and White,⁴ by Harrison and Levine,⁵ and by Seegal and Seegal⁶ indicate that rheumatic fever is commoner and more severe in the colder portions of the temperate zones than in the warmer portions. Seegal and Seegal also found that the incidence of rheumatic fever was greater from 1916 to 1918 than from 1918 to 1925. Excellent as these statistics are, they are based on diagnoses made in a variety of hospitals, and one cannot help but wonder upon what criteria the diagnoses were made. Do these statistics represent only those cases of rheumatic fever presenting arthritis, or do they include all cases of rheumatic fever? It is usually assumed that practically all cases of mitral stenosis are instances of rheumatic fever in the active, quiescent or healed stage of the disease. It is therefore very important in investigating the geographical distribution of rheumatic fever to know the regional distribution of mitral stenosis. Meleney and Kellers⁷ state that though rheumatic arthritis is rare in China, mitral stenosis is common. Harrison and Levine found mitral stenosis frequent in Boston, St. Louis and Baltimore, much less frequent in Galveston, Richmond and Oklahoma and rare in New Orleans. Wood, Jones and Kimbrough⁸ find rheumatic fever and rheumatic heart disease about half as common in Virginia as in Massachusetts. Clarke⁹

believes that rheumatic fever is almost unknown in natives in the tropics, defining the tropics as an area lying between 23° 28' North and South. He states that he did not see a single case of rheumatic heart disease among 150,000 hospital cases in Perak, Malay States. Coburn¹⁰ quotes Getz as stating that in the last 4 years only three unquestioned cases of rheumatic pancarditis have been recognized at autopsy at the Hospital of Santo Tomas in Panama. According to Coburn, rheumatic fever is extremely rare in Porto Rico. In about 500 autopsies studied by Dr. Lambert and Dr. Pappenheimer no gross or microscopic lesions of rheumatic fever were found. In a later series, however, two autopsies showing rheumatic pancarditis have been recorded.

The information, therefore, that is obtainable through published statistics and from such important personal surveys as that made by Coburn, goes to show that rheumatic fever, in all its forms, is exceedingly rare in the tropics, though rheumatic heart disease is not unknown in some tropical countries, whereas all the manifestations of rheumatic fever are common in the colder portions of the North and South temperate zones, where rheumatic arthritis is particularly prominent. In the intermediate and warmer regions of the temperate zones, rheumatic fever is certainly not recognized with as great frequency as it is in the colder regions. The geographical distribution, according to Coburn, corresponds to that of scarlet fever.

In analysing the cases at the Johns Hopkins Hospital rheumatic fever has

been considered as a generalized disease, and consequently there have been included in this category all instances of chorea, of mitral stenosis, of rheumatic pancreatitis and of rheumatic arthritis, whether they have been observed in the active, quiescent or possibly healed stages of the disease. In the majority of the cases there was some definite evidence of activity while the patient was under observation in the hospital wards. It may be seen from Table I that rheumatic fever is quite common in Baltimore, for 1.37 per cent of all patients admitted to the adult medical wards suffer from rheumatic fever. The cases of rheumatic fever, moreover, form a fair proportion of all autopsies, at least 1.66 per cent. The figures for

TABLE I ADMISSION OF RHEUMATIC FEVER TO ADULT MEDICAL WARDS Five Year Period—Sept 1st, 1925 to Oct 1st, 1930	
Total Admissions =	10,385
Rheumatic Fever =	142

Total Rheumatic Carditis =	146
Per Cent Rheumatic Carditis =	1.6

the admission rate are a little higher than those given by Faulkner and White for the Peter Bent Brigham Hospital in Boston (Table II).

Since 36 of the 146 autopsies showed rheumatic heart disease in acute or subacute form, it may be inferred that the disease may occur in Baltimore as an acute and severe infection. The total mortality for the 142 cases was 16.2 per cent. Table III shows the age incidence at the

time of observation, the occurrence of auricular fibrillation, the incidence of prolonged A-V time and the number of cases complicated by bacterial endocarditis. It is interesting to note that the proportion of patients with auricular fibrillation increases with the increase in age, and that bacterial endocarditis usually occurs in the younger individuals. The percentage of 1st, 2nd and 3rd degree heart block is small, but this is no doubt due to the fact that single electrocardiographic records were made in many instances. The figures show that delay in A-V conduction is also commoner in the younger than in the older patients, associated in all probability with the greater activity of the rheumatic process in the younger patients.

Males and females were almost equally affected, many more instances of rheumatic fever occurred in the white than in the colored race (Table IV). A careful analysis of the histories of these 142 cases and the condition on admission to the hospital discloses some interesting facts. Table V records the frequency with which various manifestations of rheumatic

fever occurred during the life of these patients before they were seen in the hospital. The past history shows that in 15 there was no history of any illness, simulating rheumatic fever and in 27, or 19+ per cent, there was no history of any rheumatic manifestation other than tonsillitis. There was a history of some form of arthritis without a history of cardiac disease in 37 patients, or in only 26+ per cent. On the other hand, cardiac disease is found to be remarkably common. In 14 cases there was a history of cardiac disease alone, and in 73 patients, or over 50 per cent, a history of cardiac disease either alone or in combination with some other manifestation of rheumatic fever. It is thus obvious that even in the histories of these patients cardiac disease is an important feature.

When one analyses the condition of the patients on admission to the hospital, the importance of cardiac disease becomes even more impressive (Table VI). Of the 142 patients, only 6 were admitted with arthritis alone and one with chorea alone. Of the entire number, 58, or only about 40 per cent, suffered with arthritis on admission, or during their stay in the hospital, while 135 or over 95 per cent, were admitted with cardiac disease or showed evidence of cardiac disease while in the hospital.

Total arthritis	58	Total cardiac disease	135

The observations upon these patients in hospital show quite definitely that many of them, though they gave no history of cardiac disease and though they were ignorant of the fact that they had cardiac disease, had had, nevertheless, cardiac disease probably for some years.

The figures thus emphasize the fact that rheumatic fever, as we see it, is essentially a disease of the heart, which may be preceded or accompanied by arthritis, often mild in character, by chorea, by tonsillitis, or occasionally by pleurisy, pneumonia, subcutaneous nodules and skin eruptions. During the acute stages the disease may be very severe or even fatal. Acute pericarditis occurred in 9 cases, acute pleurisy in 2, subcutaneous fibroid nodules were found in only 3 cases. Though many of these patients have died during the healed stage of the disease from the effects of the cardiac lesions or from such complications as bacterial endocarditis, at least 9 of the 22 autopsies showed that death was associated with some form of acute rheumatic carditis. The analyses which Dr Thayer¹¹ has made of the fatal cases of acute and subacute rheumatic fever show that fatalities during the acute and subacute stages of the disease are not very rare at the Johns Hopkins Hospital.

Table VII shows the forms of heart disease observed in the 135 cases. Al-

most all of these patients presented the signs of disease of the mitral valve. A comparatively large number also showed the signs of aortic insufficiency. In three cases the signs were those of aortic insufficiency alone, though it seems probable that mitral disease also existed in these cases. In a few instances myocarditis or chronic adhesive pericarditis was present without the signs of mitral disease.

DISCUSSION

In reviewing these histories of patients, many of whom I have studied in the wards, the fact becomes quite clear that rheumatic fever is practically as common in the hospitals of Baltimore as in the hospitals of Boston. The character of the disease is not precisely the same for arthritis in the severe form, is certainly not common in Baltimore and arthritis even in mild degree occurs in only a moderate proportion of cases. Cardiac disease on the other hand is extremely common and has been present in 95 per cent of the cases that we have studied. Patients are not often

seen in the florid stage of the disease, though severe acute rheumatic pancarditis is by no means unknown. As compared with the incidence of cardiac disease in other series of cases of rheumatic fever, the figures at the Johns Hopkins Hospital are rather high. Mackie¹² states that serious cardiac disease occurred, irrespective of age, in 68.3 per cent of his series of 393 cases of rheumatic fever, and that between the ages of 10 and 15 approximately 78.2 per cent of all cases presented evidence of cardiac disease during the first attack. Poynton¹³ found cardiac disease present in 70 per cent of 500 rheumatic children whom he examined. These figures are a high average for those found in the literature.¹⁴ At the risk of redundancy, then, it may be repeated that rheumatic fever, as seen in Baltimore, is essentially rheumatic carditis often of insidious onset, with comparatively mild acute exacerbations, but progressing none the less to a chronic deforming endocarditis with involvement of the myocardium and often of the pericardium, and resulting eventually in chronic invalidism and death. The carditis may be preceded or accompanied by attacks of arthritis, usually mild in character or by chorea.

The predominance of carditis in rheumatic fever and the insignificance of arthritis as a feature of the disease has been observed elsewhere. Meleney and Kellers have called attention to the fact that mitral stenosis occurs only a little less frequently in Peiping, China, than at St. Bartholomew's Hospital in London, and yet rheumatic arthritis is almost unknown in Peiping or in North China. Coffen¹⁵ points out that mitral disease is encountered in Ore-

gon with a frequency entirely disproportionate to the number of cases of rheumatic arthritis, and Houston¹⁶ in describing 88 cases of rheumatic fever which occurred during a period of four years amongst 115,213 general admissions to the Charity Hospital in New Orleans, emphasized the mild character of arthritic symptoms and the frequency with which cardiac disease occurred (51.1 per cent).

It seems possible, therefore, that rheumatic fever might be detected more frequently in the Southern States and in semi-tropical countries if the disease were regarded as one primarily of the heart, and if it were thoroughly appreciated that arthritis is an insignificant feature, an episode which may attract little attention or may be entirely absent.

CONCLUSIONS

The available statistics concerning the geographical distribution of rheumatic fever indicate that the disease is very rare or almost unknown in the tropics, and much less commonly observed in the warmer portions of the mid-temperate zones than in the colder portions.

In some regions where rheumatic arthritis is said to be rare, mitral stenosis is quite frequently observed.

At the Johns Hopkins Hospital in Baltimore the admission rate to the adult medical wards for rheumatic fever, in all its forms and in all its stages, over a period of five years was 1.37 per cent. The autopsy rate for rheumatic heart disease over a period of 21 years was 1.66 per cent. The disease, therefore, is comparatively common.

An analysis of 142 cases of rheumatic fever studied during this period

showed that symptoms or signs of cardiac disease appeared in the past histories of 50 per cent of the cases

Cardiac disease was present on admission to the hospital or was detected during observation in hospital in 95 per cent of these cases. Only 6 of the entire 142 cases presented symptoms and signs of arthritis alone, but in 77+ per cent arthritis, often of mild degree, occurred at some time during the illness for which they were admitted to the hospital

Rheumatic fever, as it is seen at the Johns Hopkins Hospital, is essentially

a disease of the heart frequently preceded or accompanied by arthritis often of mild degree, or by chorea. Severe acute arthritis is rarely seen but acute pericarditis and pleurisy are not very infrequent

It is suggested that the infrequency of severe acute arthritis, the great frequency of carditis and the comparative insidiousness of the disease during the acute and subacute stages renders the clinical picture of rheumatic fever somewhat different in Baltimore from that generally described for more northern sections of the United States

Colonic Changes in Chronic Arthritis*

By W H DICKSON, M D , C M , F R C P (Can), *Toronto*

THE etiology and progress of changes in the colon so often noted in arthritis have been very great controversial points. Where many different opinions are held as to the cause of a condition and many methods of treatment advanced for the alleviation of the disease, it is evident a true understanding of the basic factors has not been reached. The roentgenological observations which we report here were noted on examination of patients suffering with chronic arthritis. The investigation was carried out by the permission of Professor Duncan Graham, and with the collaboration of Dr A A Fletcher of the Department of Medicine. These observations have proved certain phases in the interpretation of the colonic disturbances, and we believe have an important bearing on the evolution of the disease.

Goldthwaite and Brown¹ pointed out the frequent observation of enteroptosis in patients suffering from chronic arthritis, and believed the enteroptosis to be either constitutional or acquired from faulty body mechanism. Assuming these premises to be correct, he and his co-workers treated many cases of arthritis by the appli-

cation of belts, improvement of posture, and regulation of the function of the bowels.

Lane² defined stasis "as such a delay in some portion of the intestine, but more particularly the large bowel, as allows the absorption into the circulation of a larger quantity of toxic material than can be dealt with effectively". The delay, he remarked, is brought about by a mechanical alteration in the drainage apparatus. Among the many clinical manifestations due to colonic stasis, he particularly drew attention to arthritis. Lane stated that in early life colonic stasis is caused by abnormal distention of the bowel through too frequent feeding, or articles of diet of an unsuitable nature. Later in life it is brought about and accentuated by the erect posture of the body. He holds this posture causes a drag upon the principal points of support, tending to the promotion of bands and kinks at these points. These bands and kinks are evolutionary and not inflammatory. Proximal to these bands and kinks he states dilatation and stasis occurs.

Lane's theory of colonic stasis is combated by many observers. Bassler³ believes these bands to be physiological and that sagging of the colon does not necessarily mean colonic stasis. Daniel⁴ holds these bands to be

*Read at the Baltimore Meeting of the American College of Physicians, March 27, 1931

due to a localized peritonitis Keith⁵ does not accept Lane's idea and denies that bands or kinks produce delay in the food stream. In defense of his statement he submits his own theory. He has noted in the myenteric plexus, or rather intermediate between the plexus and muscular fibres, certain cells partaking of the character of nerves and muscle. This he calls nodal tissue because of its close resemblance to the nodal tissue in the heart. His suggestion is that irregularities in impulse conduction may occur in the nodal system of the colon, and cause stasis as in heart block. We have also noted marked improvement in colonic tone during spinal anesthesia and following a section of the lumbar sympathetic branches.

Jordan⁶ who long supported Lane stressed the roentgenological evidence of drags at the ligament of Treitz, kinks, and bands in the last part of the terminal ileum, the hepatic flexure, the splenic flexure and the sigmoid. These he states are evidenced by a constriction of the lumen of the bowel at the site of involvement, limitation of movement on forced inspiration, on palpation and with postural change. Jordan's investigation for years formed the ground-work for roentgenological study of the colon in colonic stasis and colonic dilatation.

Rae Smith⁷ recently discussed the relation of the pathology of the right lower quadrant to arthritis, paying particular attention to the blue thin-walled toneless cecum and has obtained relief following plastic operation upon the large bowel. He emphasizes the presence of constricting bands upon the ascending colon, believing the etiology

of the constriction to be due to faulty fusion in the last stage of migration, rotation and descent of the colon. As a result of the faulty fusion we have a *cecum mobile* and an ascending colon possessing a mesentery. He states "Given this faulty fusion we have the stage set for a long chain of events. Starting with the loss of tone due to advancing years or a long strain due to illness, we have a loss of the lumbar curve, that is the shelf on which the cecum rests. With the loss of the curve the cecum tends to prolapse. In an effort to correct the position of the prolapsing cecum nature starts the growth of a membrane at the site of the right colic artery on the mesentery side. This attaches the colon to the side wall by a reduplication of the peritoneum the colon is rolled and twisted pressure on the myenteric plexus results (here he evidently supports Keith's theory), a spasticity of the distal bowel results, with atony of the proximal portion, the cecum and the ascending colon."

Taylor⁸ collaborating with Smith minutely describes the technique used in the roentgenological demonstration of these changes, and in an illuminating manner gives his interpretation of the screen and film findings. We are heartily in accord with Taylor's findings. On many occasions have we demonstrated the cecum low in the pelvis atonic to boggy and on palpation have demonstrated a marked mobility raising the cecum at times to a point where it may be superimposed upon the splenic flexure. The deformity of the ascending colon also is often seen due to the membrane described by Smith, and the spastic distal

bowel is easily demonstrated. Occasionally at the six-hour examination the head of the meal will be present in the sigmoid, the colon from the site of the veil on the ascending colon to the sigmoid presenting the so-called "string type"

Our experience however has not allowed us to arrive at the same conclusions as Drs Smith and Taylor. Of the large number of our cases giving the roentgenological findings described by them, very few indeed presented any evidence of arthritis, nor were we able to elicit a history of any attacks simulating that disease. On the other hand, in the many definite cases of arthritis that it has been our

privilege to examine in collaboration with Dr Fletcher, very few indeed have shown changes analogous with those observed by Dr Taylor.

While it is the generally accepted theory that arthritis is as a rule secondary to some focal infection, the belief has been held to a degree that diet, or rather improper diet, has some relation to arthritis. Pemberton⁹ advised diets low in calories and restricted in carbohydrates, and my colleague in this investigation, Dr Fletcher,¹⁰ has stressed the use of diets high in vitamins and low in carbohydrates.

McGarrison¹¹ in his work on animals showed that atony of the colon

FIG 1

FIG 2

FIGS 1 and 2 Miss C, aged 17. Pain and swelling of the metacarpal joints for ten years. During summer of 1928 arthritis developed in knees, ankles, and shoulders. No history of sore throats and no focus of infection found. Admitted to hospital September 29, 1928 with moderately severe arthritis of rheumatoid type and also aortic mitral valve lesions with moderate cardiac hypertrophy. Changes are shown which occurred in the colon over six weeks of dietetic treatment. Marked improvement in the arthritis occurred during this time.

can be brought about by diets deficient in vitamin B, and suggests that the disturbance of mobility and tone in the lower bowel might be of nutritional origin. Using these results of McGarrison as a basis, we attempted to repeat his work, using white rats as our subjects and making our observations by the use of the barium enema.

Normal rats, well nourished and fed upon a diet rich in vitamin B, were given barium enemas. After this examination a diet deficient in vitamin B was exhibited for several weeks, when a second enema was given. The diet was again returned to one high in vitamin B and a third enema administered in a month's time.

The colon underwent marked changes during the observation. The second examination showed the bowel elongated and very atonic, so atonic in fact that the pressure from the flow of the enema was great enough to rupture the colon, and the enema poured out into the abdominal cavity. The rats we were fortunate enough not to lose by this accident were at once placed on a diet again rich in vitamin B and further observation made in a month's time.

At the third observation the tone of the bowel had returned to normal appearance, and it was much shortened in its total length. In some of the rats it was difficult to demonstrate any difference between appearances at the first and at the third enema.

FIG 3

FIG 4

FIGS 3 and 4 Mrs. D., age 44. Moderate degree of osteoarthritis of three years' duration. Blood pressure 178/108. Picture shows changes which appeared in the colon during two months of dietetic treatment. Well marked improvement took place while on this treatment.

With this point before us, it was assumed that some of the abdominal disturbances of chronic arthritis might be associated with nutritional deficiency, and at the request of Dr Fletcher this investigation was undertaken in an attempt to prove or disprove the theory. Our first step was to demonstrate the incidence and type of colonic abnormalities in arthritic cases. When this had been done, we proceeded by periodical examinations, to demonstrate the effect of suitable diet upon the clinical progress, and the roentgenological appearance of the large bowel. In many cases the return to a normal appearance was indeed amazing. In others, and these were, we believe, complex cases, where nutrition alone played only a minimum part, the changes were slight or absent. It was, however, extremely interesting to note that in the majority of cases the improvement noted on the film bore a close relation to the improvement noted clinically. Latterly, we have been able with a very fair degree of accuracy, to state from the roentgenological examination, the amount of improvement, shown clinically, without any progress history being supplied from the clinician. Also, it has been possible after the first examination in some cases to give a prognosis pointing towards failure that has been borne out by the patient's subsequent course.

The roentgenological investigation may be carried out by use of the barium meal or the opaque enema. By the meal, the rate of progress or mobility will be demonstrated, and we must say we prefer the one-meal method to the two-meal one. In us-

ing the former, observations are made at the time of ingestion and at periods of six, ten, twenty-four, forty-eight, and seventy-two hours. If this is done a better understanding of the motility in each case will be obtained. The ten-hour observation is of great value. The head of the column has passed beyond the splenic flexure, the right lower quadrant is not obscured by coils of small bowel, and the appendix if filled is better seen and manipulated than at the six-hour observation.

In the vast majority of the arthritic cases examined, we saw no undue racing of the meal, the time of advance of the column's head being quite normal. In the cases showing hypermotility and spasticity, we were frequently able to demonstrate the constricted ascending colon due to a veil, and the markedly atonic cecum, but these cases indeed were few. The cecum was low in the pelvis, atonic in type, but not unduly free, demonstrating that no abnormal mesentery was present. The position of the ileocecal valve when demonstrated by an incompetency was normal, thus showing no rotation. The appendix when visualized, in very few of the cases was placed retroceally, or in an abnormal position. The ascending colon appeared well filled, often longer than usually seen, no narrowing was observed, and the haustral markings were much decreased in depth. The transverse colon showed an increase in length, often festooned in type, the haustral markings poor, or entirely absent, and the so-called "H" formation was conspicuous by its absence. The descending colon shows a definite increase in length, varying from a slight

elongation to a marked redundancy, and reduplication with lessened haustral markings

The enema gives much more evidence in our opinion than the meal, and in our re-examining of any case, the clysma is administered at intervals of about one month, comparing the various films at the completion of each examination

Might we stress here the value of the fluoroscopic screen in conjunction with the film. During the flow of the clysma under the screen, the whole bowel may be palpated. The chance of not observing any evidence of narrowing, adhesions, veils or rotation, is to a great degree eliminated. Occasionally mass peristalsis will occur after the screen examination, and when the film is made the evidence has been obscured by this. The cecum will fill well, it will be placed low in the pelvis, and marked lack of tone is noted. The transverse diameter of the cecum will be increased, and the enlargement will be noted extending to a greater or less degree up the ascending colon. No narrowing of the ascending colon will be seen that may be due to a veil, nor do we see evidence of rotation.

The hepatic flexure as a rule may be noted about the level of the first lumbar vertebra, but occasionally in the very advanced cases it will be displaced downwards. When the transverse colon fills, it will be noted the haustral markings are lessened or absent, and the transverse diameter of the bowel is increased. The total length of the transverse is also greater than usually seen, and instead of the usual "H" appearance presented by the hepatic flexure the transverse colon

and the splenic flexure, the bowel has assumed an irregular festooned position across the abdomen. The splenic flexure is held in about its usual position, but in the more advanced cases, we have noted a downward displacement there.

The descending colon shows a redundancy in many cases, frequently complete reduplication of the bowel will be noted, and tone has become less, with haustral markings poor. In the cases showing extreme change, a complete disorientation of the colon is noted.

As mentioned above, re-examination has been carried out on a large number of these cases. These examinations are spaced about one month apart. The findings at these periods were in many cases very gratifying indeed. At these observations the cecum is held at a higher level in the pelvis, the transverse diameter is lessened, and haustral markings are returning. In some of the cases this is very marked. The ascending colon shows better haustration and on measuring the longitudinal diameter of the cecum and ascending colon we have noted a decrease of as much as two inches. The transverse colon presents a lessened transverse diameter its total length is decreased and the haustral markings are improved. This shortening of the ascending and transverse colon leads one to believe the longitudinal fibres play a definite part in the changes taking place. The festooning has disappeared and a return toward the "H" type is noted.

The descending colon presents its changes also. The reduplication will be noted to have lessened in extent.

tone has improved, and haustration is better. The appearance present throughout the whole colon is that of increasing tone, returning to or at least approaching the appearance of a normal tonic colon.

In reviewing the cases examined, of which we now have about two hundred in the department, the changes mentioned above were present in 66 per cent, and improvement was present in a great majority. Coincident with the improvement of the roentgenological appearance, the clinical picture also gives a definite change for the better, reaching in some a complete amelioration of the symptoms.

All of these cases have been ob-

served under careful control. Some had been confined to bed for many months, previous to the institution of treatment. One or two were not confined to bed at any time during the investigation. At the time that dietetic treatment was undertaken all other remedial measures were discontinued, or had never been instituted.

From the foregoing observations, there seems to be no doubt that tone and motility of the large bowel are dependent on the nature of the diet, and in cases of atony definite improvement may be expected by these dietetic measures. Further, the improvement in the general condition of the patient and the amelioration of the

FIG 6

FIGS 5 and 6 N. B., aged 26. Rheumatoid arthritis started in 1922. Some improvement in 1924 following tonsillectomy. Later disease became more severe and from 1926 was confined to bed. Admitted May 28, 1928, showing advanced fibrous change in knees and ankles, ankylosis of hips and atrophy of muscles and bone. No further focus of infection found. The changes shown above occurred during four months of dietetic treatment. There has been slow but continued clinical improvement during the course of dietetic treatment.

symptoms coincident with the changes demonstrated by the roentgenological observation, leads us to believe that malnutrition is playing a part in the clinical picture of arthritis, and those atonic changes are a definite expression of the malnutrition.

These investigations have been carried out upon patients with rheumatoid-arthritis and osteoarthritis, and the colonic changes above described have been present in both types. The rheumatoid-arthritic group has shown the greater colonic changes and the more

improvement under dietetic treatment. We do not wish to create the impression that we consider the colonic changes described above as the primary abnormality, rather they are indicative of some other pathological process of more importance, due to nutritional deficiency, which is an important factor in the evolution of arthritis.

Dr Fletcher has followed two general principles in his dietary treatment of these cases. First the liberal ad-

FIG. 7

FIG. 8

FIGS 7 and 8. A. E., was in the hospital from Dec. 3, 1930 to Feb. 28, 1931. Five or six years ago patient began to develop pain and swelling of various joints of body with some limitation of movement. Four years ago had developed marked limitation of movement of right shoulder-joint following radical breast amputation (for scirrhous carcinoma). Arthritic involvement was in right elbow first then left wrist, right and both knees and ankles and then left shoulder. More recently within last 2 years both hands have been involved (small joints). Shortly after onset of joint pains had teeth and tonsils removed. Three weeks before admission patient first noticed swelling over sternum which was prominent (at right sterno-clavicular joint) on admission. Swelling it slightly reddened and tender. This swelling largely subsided in hospital and there was moderate improvement in other joints. Marked improvement in arthritis during residence in hospital and definite improvement in colon as shown in the films.

ministration of vitamins, especially vitamin B, secondly, a change in the balance of diet. He gives liberally food high in vitamins such as fresh vegetables and fruits, cream, butter, eggs and liver, and vitamin B is increased by administration of baker's

or brewer's yeast or wheat germ. The last appears the more effective upon these disturbances of the colon. Fifty to sixty grams of protein are given in the form of meat, fish, eggs, or liver. Fat is exhibited according to the patient's caloric requirements.

Total Occlusion of the Right Branch of the Pulmonary Artery By An Organized Thrombus*†

By J H MEANS, M D, F A C P, and T B MALLORY, M D,
Boston, Mass

THE following case, because of the apparent rarity of one of the lesions found, total thrombotic occlusion of a main branch of the pulmonary artery, and the interest of its physiological connotations, is considered worth reporting

The existing literature contains but few cases of such occlusion of a main branch, although multiple thromboses of the smaller arteries appear fairly common. A case of that sort has recently been reported by Frothingham.¹ A monographic article by Posselt² in 1909 reviews thoroughly all types of pulmonary artery disease, and may be considered to cover the literature up to that time. He was able to find only three cases of complete occlusion of the pulmonary artery or one of the major branches.

The first was that of von Jurgensen. It may be summarized as follows:

The patient was a male, sixty years of age who had had dyspnea for several years which had become distinctly troublesome during the last six weeks. Physical examination showed dyspnea and marked cyano-

sis, respirations 40, pulse 88, beat irregular and distinctly intermittent. The lungs were emphysematous. The heart was enlarged to percussion, especially to the right. The sounds were all weak, but the pulmonic seemed especially weak in comparison with the aortic. There was sclerosis of the peripheral arteries. The day after entry he had a sudden slight hemiplegia with left facial paralysis and difficulty in speech. During the following two days indefinite pulmonary signs developed which were associated with a bloody sputum and it was thought he probably had pneumonia. On the third day he suddenly developed convulsions and died.

Autopsy showed the main trunk of the pulmonary artery completely occluded by a pale, reddish-gray thrombus, one inch in length, which was loosely but definitely adherent to the wall. Attached to it were several smaller, redder and fresher looking thrombotic masses. They were less adherent than the large, grayish mass. The right pulmonary artery also contained a completely occluding older thrombus, which was also adherent. The vessels in the region of the thrombi showed patches of atheroma. The heart was enlarged with hypertrophy of both ventricles. Thrombi were present between the columnar cardiac in the right ventricle. The valves showed no abnormality. The lungs showed interspersed areas of emphysema and collapse. A few small infarcts were present. An acute military tuberculosis was found with tubercles in the lungs, liver, bronchi and retroperitoneal glands. No evidence of hypertrophy of the bronchial arteries was found.

*From the Medical Clinic and Pathological Laboratory of the Massachusetts General Hospital.

†Received for publication May 27 1931.

though von Jurgensen assumes in his discussion that the lungs must have been nourished in this way

Posselt also found two cases reported by Hart. They were in brief as follows

Case I A woman with signs and symptoms of heart disease consisting of a mitral systolic murmur, dyspnea and cyanosis, particularly of the fingertips, died under observation in the hospital with symptoms of gradually increasing decompensation

The autopsy showed marked cardiac hypertrophy of both the left and right sides of the heart. There was a well marked mitral stenosis with a fresh verrucose endocarditis. A thrombus was found in the pulmonary artery which completely occluded the main stem and the right primary branch and partially occluded the left primary branch. It showed definite lamellation and evidently had been deposited in layers. There was well marked organization at the periphery. The lungs showed extensive pleural adhesions. They were normal in volume, only slightly increased in consistency, crepitant throughout, and very rich in blood

Case II A man with symptoms of tabes dorsalis of five years' duration developed a pyelonephritis. Three weeks before death he developed what was apparently a slight bronchitis but associated with it was a marked impairment of his general condition ("Störung des Allgemeinbefindungs")

At autopsy a pale, grayish-red thrombus with indistinct lamellation was found which completely occluded the main stem and the right primary branch and partially occluded the left branch. There was no cardiac hypertrophy. The lungs were of normal volume, air-containing throughout and hyperemic. In the iliac vein an older, totally occluding thrombus was found. Microscopic examination confirmed the organization at the periphery of the lungs in both cases. In neither case was an increase in diameter of the bronchial artery demonstrated

Barnes and Yater in 1929 reported a case of thrombosis of the large pulmonary arteries

A man of 34, was seen first in August, 1926, when he complained of dysphagia and vomiting associated with marked dyspnea on effort. Fifteen months previously he had had a septicemia following a hand infection, and four months previously a sudden attack of pain in the left chest, worse on deep breathing, and a week later similar pain on the right. Examination revealed no adequate explanation of these complaints. A positive Wassermann was found and anti-luetic treatment was given. He gradually improved and got back to work. In the autumn of 1926 there was some suggestion of lung abscess, but this did not persist

On re-examination in March and October, 1927, and March, 1928, there was found evidence of congestive heart failure, marked cardiac hypertrophy and gallop rhythm. The pulmonic second sound was greatly accentuated and the electrocardiogram showed right ventricular preponderance. He gradually became more and more dyspneic and edematous and died of progressive cardiac failure in September, 1928. In the late stages of his illness he developed an erythrocytosis

The significant autopsy findings were old thrombi in the main trunk of both pulmonary arteries and hypertrophy of the right ventricle. The thrombi were dense, white masses, about 4 cm long and 0.5 cm-1.0 cm in diameter, in the pulmonary arteries between the main trunk and the subdivision of the arteries into their branches. These thrombi greatly reduced the lumina of the arteries, the right more than the left. They were firmly adherent to the walls. The arteries were not sclerotic and appeared to be dilated. The heart valves were normal except for the mitral, which showed some verrucose, rheumatic endocarditis. The coronaries were not sclerosed but appeared dilated. Some chronic adhesive pleuritis (bilateral) and pericarditis were found, also bronchiectasis with abscess-formation in the base of the upper right lobe. Grossly the lungs showed little other evidence of disease

The authors comment on the unusual problem in diagnosing serious heart failure without obvious expla-

nation There had been no evidence of valvular, hypertensive, or coronary disease The cardiographic findings and the loud pulmonic second sound led to a diagnosis of cardiac failure, chiefly of the right heart, due to some obstruction in the pulmonary circuit The finding of the pulmonary thrombosis made it clear that the history of seizures of pain in the chest with dyspnea denoted embolism The obstruction of the pulmonary circulation by the subsequent thrombosis threw extra work on the right heart and caused failure

Jump and Baumann⁴ have also published a case of pulmonary artery thrombosis with chronic cyanosis and polycythemia

A man of 48 was admitted to the Philadelphia General Hospital complaining of swelling of the legs of two weeks' duration He had also more recently had dyspnea and palpitation on effort On examination he showed slight edema and very marked cyanosis of the face, especially dark around the nose and lips There was also moderate cyanosis of the extremities The heart was not enlarged and there was a soft systolic blow at the apex, not transmitted The liver was palpable 5 cm below the costal margin The pulse ranged from 60 to 80 and the red blood cell count varied from 5,200,000 to 7,700,000 The blood pressure was 130/80 The electrocardiogram showed right ventricular preponderance After two months in a stationary state, except for gradually increasing cyanosis he died with signs of right heart failure

The autopsy showed right ventricular hypertrophy and dilatation The pulmonary artery was dilated About two inches from the orifice was a large thrombus attached to the posterior wall and extending into both branches The left side of the heart was not remarkable the valves were normal The left lung was voluminous markedly congested and dark purplish-red in color Section of the pulmonary artery showed con-

siderable thrombotic material firmly attached to the walls and extending to the smaller subdivisions The thrombus was large enough almost to occlude the vessel Underlying it there was some arteriosclerosis The right lung was congested and also showed some tuberculosis The right branch of the pulmonary artery showed the same changes as the left, i.e., marked thrombosis and moderate arteriosclerosis The liver and spleen showed chronic passive congestion The first portion of the aorta showed moderate arteriosclerosis Jump and Baumann point out a close resemblance between the symptomatology in their case and that of so-called Auer's disease

More recently Brenner⁵ has reported six cases in which were found thromboses of large branches (not main branches) of the pulmonary artery In all but one there was microscopic evidence of organization of the thrombi This author concludes that the thrombosis usually occurs after severe congestive failure has set in and produces no evident additional symptoms, though it probably hastens the end

Our own case is as follows

CASE REPORT

An American business man of 60 entered the private ward of the Massachusetts General Hospital as the patient of one of us (J. H. M.) on November 11, 1929 obviously in a terminal stage of congestive heart failure

No history of rheumatic disease could be obtained and it was quite certain that he had never had syphilis He had for some years been a patient of Dr. James B. Herrick of Chicago to whom we are indebted for considerable information Among other things Dr. Herrick wrote us the following

"He came to me first in 1905 for a probable entirely unrelated to his heart

At that time I recorded in 1905 a small murmur I did not see him again for ten or twelve years but have seen him on several times since I have been in

he was laid up with an attack of renal colic with marked hematuria. The X-ray showed stone. Both Dean Lewis and I felt in view of his heart condition and the comparative harmlessness of the stone in the kidney that an operation should not be done."

In 1922 he had an operation upon his thyroid by Dr J M T Finney of Baltimore. He had had a goiter for several years and it was apparently a familial affair occurring also in three or four of his immediate relatives. Dr Finney wrote to us as follows: "He presented himself to me in the summer of 1922 with large, toxic, multiple adenomata of the thyroid. He was suffering from pressure on the trachea, as well as from toxemia.

"Although he was not a good risk, I advised operation, which was done in June, 1922. The thyroid proper was pretty well displaced by several large adenomata, which involved pretty much the whole gland. They were partly sub-sternal and partly above, displacing the trachea quite markedly. Operation was made more difficult on account of free bleeding from the large vessels, as well as from the size of the gland, and from the fact that a large adenoma was retro-sternal and could be delivered with difficulty. Only a small portion of the glandular tissue was left, that was posterior, and was thought to be sufficient to provide function as well as to insure no injury to the parathyroids." He made a satisfactory recovery, and some dyspnea which had been present before operation disappeared. In fact he became wonderfully well.

In other respects the past and family stories seemed unimportant.

The symptoms which led up to his final illness began in September, 1928, with slight dyspnea on effort. This was relieved for a time by digitalis. In November, 1928, according to Dr Herrick, "he had an acute and very violent respiratory tract infection, resembling in every respect the influenza we had in 1918. His temperature was about 105°. He had no leucocytosis. There was definite consolidation in patches. He became extremely cyanotic and orthopneic and it looked as though he were going to die. He was pretty heavily digitalized and he pulled through."

He made some improvement after the infection, but was never really well again. In January, 1929, he got to Florida, but the trip tired him so badly that he led a bed or wheel chair existence there. He was having definite cardiac symptoms, dyspnea, and edema of ankles. In March he was moved to Atlantic City where he stayed in bed for two months on digitalis, with a slow and gradual improvement. During this time he had several nosebleeds. In May he went to his summer home in Vermont. After arriving there he stayed in bed for two weeks on digitalis and a restricted diet. By the middle of June he was much better, he could lie flat, breathe fairly well and walk slowly about the garden.

This improvement was maintained until the beginning of October, when his dyspnea and edema of his lower extremities returned, gradually increasing in degree. From October 10 on he had orthopnea and during the two weeks or so prior to entry, gradually increasing cyanosis. He had had practically no cough or sputum and no pain in the chest or palpitation. There had been some attacks of restlessness at night, but no sudden dyspnea, choking or wheezing. No headache, visual disturbance, nausea or vomiting had been present. There had been considerable heartburn. He had had nocturia, once per night, during the summer, with apparently a fairly normal total output of urine.

As he was steadily getting worse it was decided to transfer him to the Massachusetts General Hospital.

On arrival (November 11), after an one hundred and fifty mile motor ride, which he stood surprisingly well, examination showed him to be a cyanotic, orthopneic man with Cheyne-Stokes breathing and pin point pupils (morphine). The cyanosis was of medium intensity and generalized. The heart was enormous, the left border being in the mid-axillary line and there was a heaving impulse over a wide area in the sixth and seventh interspaces. No enlargement to the right was made out, nor any increase in supracardiac dullness. There was a loud, double murmur audible over the entire precordium and outward along the clavicles and, to a slight extent, up into the neck.

This double murmur was most loudly heard in the aortic area. At the apex there were three blowing murmurs giving a gallop sound. The only normal heart sound heard was a rather weak P_2 . No friction or thrills were made out. The rate was 82 and the rhythm regular. The blood pressure varied from 140 to 170 systolic over 20 diastolic. The neck veins were somewhat engorged.

The lungs were surprisingly clear. There was good resonance throughout with normal breath sounds. There were a few crackles at each base. The abdomen was slightly distended, but otherwise negative. The liver was not felt. There was moderate, soft edema of both lower legs, lower back and inner aspects of the thighs, but not of the scrotum. In all other respects the physical examination seemed unimportant. The scar of thyroidectomy was noted in the neck, but no evidence of thyroid tissue was discovered.

In hospital through November 13 his condition remained critical but without important change. Digitalization was maintained and in addition theocine was given. No diuresis was produced. The outstanding difficulties were the respiratory distress and cyanosis, and yet no physical signs of importance could be discovered in the lungs.

On November 14, after large doses of caffeine, the Cheyne-Stokes breathing gave way to an equally distressing type of regular breathing. On that day there was noted some edema of the left arm, and the temperature which had been subnormal until then, rose to 103°F . He gradually sank into a stupor, the breathing became very jerky and on the morning of November 15 he died. The pulse rate of 100 at entry rose to 120 the morning of his death.

The laboratory work obtained during this brief stay in hospital was as follows. Four examinations of the urine showed specific gravities of 1.020 to 1.030, a large trace of albumin in all specimens, sugar in none. The urines were all acid and cloudy and the sediments all showed red blood cells, white blood cells and many hyaline casts. The white blood cell count on November 12 was 19,700 and on the 14th, 17,000. The non-protein nitrogen of the blood on November 12 was 66 mg per 100 cc. The Hinton

test on the blood was negative. The electrocardiogram showed a regular rhythm rate 100, with slurred QRS in all leads, moderate left axis deviation, intraventricular block, probably right bundle branch type, also auricular-ventricular block and upright T_1 and T_2 and diphasic T .

The *clinical diagnosis* was arteriosclerotic and hypertensive heart disease with dilatation and marked hypertrophy of the heart, aortic valve disease with regurgitation, congestive failure, chronic passive congestion and terminal bronchopneumonia. The last was by inference only since no physical signs of pneumonia had been found. The nature of the aortic lesion was thought to be arteriosclerotic, since no evidence whatever of either syphilis or rheumatic infection had been obtained. This note was also made before death: "The deep cyanosis would suggest some factor in the lesser circulation but the lungs are surprisingly clear showing only a few unimportant crackles at the base." Congestive failure was regarded as the chief cause of death with bronchopneumonia a contributory cause.

The *post mortem examination* showed a remarkable variety of unusual lesions. The most striking was a complete thrombotic occlusion of the right pulmonary artery. Beginning exactly at the bifurcation the artery was completely filled by a reddish-gray somewhat friable adherent mass which extended about a centimeter into each of the three main branches of the artery within the hilus of the lung. There was no evidence either grossly or microscopically of canalization but the character of the clot and its degree of organization at the periphery suggested that it must have been pass-

he was laid up with an attack of renal colic with marked hematuria. The X-ray showed stone. Both Dean Lewis and I felt in view of his heart condition and the comparative harmlessness of the stone in the kidney that an operation should not be done."

In 1922 he had an operation upon his thyroid by Dr J. M. T. Finney of Baltimore. He had had a goiter for several years and it was apparently a familial affair occurring also in three or four of his immediate relatives. Dr Finney wrote to us as follows: "He presented himself to me in the summer of 1922 with large, toxic, multiple adenomata of the thyroid. He was suffering from pressure on the trachea, as well as from toxemia.

"Although he was not a good risk, I advised operation, which was done in June, 1922. The thyroid proper was pretty well displaced by several large adenomata, which involved pretty much the whole gland. They were partly sub-sternal and partly above, displacing the trachea quite markedly. Operation was made more difficult on account of free bleeding from the large vessels, as well as from the size of the gland, and from the fact that a large adenoma was retro-sternal and could be delivered with difficulty. Only a small portion of the glandular tissue was left, that was posterior, and was thought to be sufficient to provide function as well as to insure no injury to the parathyroids." He made a satisfactory recovery, and some dyspnea which had been present before operation disappeared. In fact he became wonderfully well.

In other respects the past and family stories seemed unimportant.

The symptoms which led up to his final illness began in September, 1928, with slight dyspnea on effort. This was relieved for a time by digitalis. In November, 1928, according to Dr Herrick, "he had an acute and very violent respiratory tract infection resembling in every respect the influenza we had in 1918. His temperature was about 105°. He had no leucocytosis. There was definite consolidation in patches. He became extremely cyanotic and orthopneic and it looked as though he were going to die. He was pretty heavily digitalized and he pulled through."

He made some improvement after the infection, but was never really well again. In January, 1929, he got to Florida, but the trip tired him so badly that he led a bed or wheel chair existence there. He gradually sank into a stupor, the breathing became very jerky and on the morning of November 15 he died. The pulse rate of 100 at entry rose to 120 the morning of his death.

The laboratory work obtained during this brief stay in hospital was as follows. Four examinations of the urine showed specific gravities of 1.020 to 1.030, a large trace of albumin in all specimens, sugar in none. The urines were all acid and cloudy and the sediments all showed red blood cells, white blood cells, and many hyaline casts. The white blood cell count on November 12 was 19,700 and on the 14th, 17,000. The non-protein nitrogen of the blood on November 12 was 66 mg per 100 cc. The Hinton

test on the blood was negative. The electrocardiogram showed a regular rhythm, rate 100, with slurred QRS in all leads, moderate left axis deviation, intraventricular block, probably right bundle branch type, also auricular-ventricular block and upright T_1 and T_2 and diphasic T_3 .

The *clinical diagnosis* was arteriosclerotic and hypertensive heart disease with dilatation and marked hypertrophy of the heart, aortic valve disease with regurgitation, congestive failure, chronic passive congestion, and terminal bronchopneumonia. The last was by inference only since no physical signs of pneumonia had been found. The nature of the aortic lesion was thought to be arteriosclerotic, since no evidence whatever of either syphilis or rheumatic infection had been obtained. This note was also made before death, "The deep cyanosis would suggest some factor in the lesser circulation but the lungs are surprisingly clear, showing only a few unimportant crackles at the base." Congestive failure was regarded as the chief cause of death with bronchopneumonia a contributory cause.

The *post mortem examination* showed a remarkable variety of unusual lesions. The most striking was a complete thrombotic occlusion of the right pulmonary artery. Beginning exactly at the bifurcation the artery was completely filled by a reddish-gray, somewhat friable, adherent mass which extended about a centimeter into each of the three main branches of the artery within the hilus of the lung. There was no evidence either grossly or microscopically of canalization, but the character of the clot and its degree of organization at the periphery suggested that it must have been pres-

ent weeks or possibly months. The right lung, however, showed no trace of necrosis or of scarring. It contained much less blood than the left lung, which presented the usual picture of chronic passive congestion. It was smaller and slightly less crepitant than the left, yet it contained air throughout all portions and showed no evidence of collapse.

The absence of necrosis could of

course be explained only by the development of a compensatory circulation. Evidence of this was readily found. Three arteries of unusual size led into the hilus region. The first was evidently a greatly hypertrophied bronchial artery, estimated to be four times the diameter of the normal bronchial artery. Two other vessels of unusual size compared with control specimens, ran along the sides of the

FIG. 1. Anterior view of the lungs one-third the original size. The right pulmonary artery has been opened to show a completely occluding thrombus, which on microscopic examination showed early organization at its periphery. The right lung is slightly smaller than the left but shows no infarction.

trachea anastomosing at their lower ends with the hypertrophied bronchial artery, and passing into the right hilus. They were traced upwards into the neck where they probably arose from the inferior thyroid arteries which supply the trachea, though the dissection was not carried high enough to demonstrate their origin.

Further examination of the right lung revealed several other findings of interest. In the region of the hilus was an irregular, pyramidal, calcified and partially ossified mass approximately 3 by 3 by 2 cm. It completely surrounded the primary bronchial branches which passed unobstructed through the area, though their walls were calcified. It also surrounded the first branches of the pulmonary artery which passed through the area without narrowing of their lumina. They were, however, occluded by thrombi continuous with the large thrombus in the main artery, but in this region the clot was redder, softer, less adherent and apparently of more recent origin. Microscopic examination of this region showed a mass of almost acellular, hyalinized and partially calcified, fibrous tissue in which were numerous foci of ossification containing well differentiated bone trabeculae separated by fatty and, in places, hematopoietic marrow. No foci of caseation and no areas suggestive of tuberculosis could be identified.

The pulmonary arteries beyond the point of thrombosis were entirely normal in appearance until the peripheral portion of the lung was reached, where many were found partially or completely occluded by fibrous plugs typical in appearance of completely organ-

ized thrombi. Many of these showed canalization. It is particularly interesting that exactly similar lesions were found in corresponding peripheral portions of the left lung.

The capillaries of the alveolar walls were difficult to make out, and very few red blood cells were found in the septa. The lumina of the alveoli, which in the congested left lung contained hemosiderin-filled "heart lesion cells", serum and occasional red blood cells, were for the most part empty or contained a mucoid secretion. The epithelium of many of the alveolar sacs showed a metaplasia into a high cuboidal or even low columnar type.

The other finding of greatest importance was in the heart. It was greatly hypertrophied, weighing 995 gm. The hypertrophy was shared between the two ventricles, both of which were greatly dilated, their walls hypertrophied. The right ventricle was proportionately slightly more hypertrophied, its walls measuring 7 mm in thickness, whereas the left measured 16 mm. Both auricles showed moderate dilatation. The aortic valve was bicuspid—evidently a congenital lesion. It also showed marked calcification of both its cusps so that they were practically immobile and fixed in a position to cause both stenosis and regurgitation. The other valves were negative and the coronaries showed only occasional patches of atheroma without narrowing of the lumina.

A substernal colloid goiter weighing 75 gm and a smaller separate one weighing 5 gm were found in the anterior mediastinum above and anterior to the great vessels. It was not felt that they played a part in the symp-

FIG. 2 The hilus of the lung viewed from behind with the trachea and primary bronchi laid open. The aorta has been dissected free and reflected laterally to show the greatly hypertrophied bronchial artery passing behind the hilus glands.

tomatology An incidental finding was a calculus in the right renal pelvis with an adjacent papilloma of the epithelium

DISCUSSION

The variety of unusual lesions found in this patient makes attempts at interpretation of their interrelations both interesting and baffling. Congenital bicuspid valves are ordinarily competent and the stenosis and regurgitation, evidence of which was noted first at the age of thirty-six, must be considered an acquired lesion. Syphilis was readily ruled out by the serologic studies in life and by the autopsy findings. The process might have been either rheumatic or arteriosclerotic in origin, the latter seeming to us more consistent with the anatomic findings, with the absence of mitral involvement, the late onset, and the lack of history of rheumatic fever.

The renal stone was evidently a side issue and the goiter, past history with no probable bearing upon the present illness.

The complete plugging of the pulmonary artery without necrosis, with the probable duration of life of weeks to months since its occurrence struck us as quite remarkable. Two possibilities came up for consideration, the local formation of the thrombus, or an embolus from some undetermined source. Local thrombus formation almost always presupposes local vascular injury. It was not thought that the calcified mass in the hilus of the lung could have been responsible, for although it completely surrounded the chief branches of the artery, it did not narrow them and their inner surfaces were in no way involved. On the

other hand it seemed fair to assume that an embolus could not have been totally occluding from the start since so sudden a strain upon an already damaged heart would almost certainly have been immediately fatal, or would have produced clinical symptoms of which we have no suggestion in the history. A medium sized embolus might well have lodged in the right pulmonary artery producing at first only a partial occlusion, but gradually growing by accretion into a mass which completely filled the artery. This would have allowed time for the development of the rich compensatory circulation supplied by the hypertrophied bronchial artery and the anastomosing tracheal branches. The numerous partially or completely obliterated branches of the pulmonary artery found in the peripheral portions of both lungs might be the result of a shower of minor emboli which had been completely organized and partially canalized.

The case is interesting from the point of view of morbid physiology in that it proves that an entire lung may be separated from its pulmonary artery supply and suffer no injury of any sort provided the occlusion is gradual, allowing time for the establishment of a collateral circulation from the aorta. The situation reminds one of those cases of chronic total occlusion of both coronaries without history of the characteristic picture of coronary occlusion. The effect of slow closure of the pulmonary artery is evidently different from sudden shutting off, as from embolism or ligation, in which cases the picture of infarction is produced. Sauerbruch

and Bruns⁶ experimentally found that even a main branch could be tied without disastrous consequences, but that fibrosis and shrinkage of the lung developed forthwith. They also have shown that in man in cases of bronchiectasis and tumors there is produced a marked shrinkage of the lung. Lilienthal⁷ describes one ligation of the left main branch within the pericardium for abscess. The patient survived the ligation but soon afterwards drowned in pus from the abscess.

With regard to the collateral bronchial arterial circulation the work of Holman and Mathes⁸ is of interest. These investigators found marked dilatation of the bronchial artery supplying a lobe containing an experimentally produced abscess.

From the clinical point of view it is of interest that such a gross disturbance in lung circulation can exist without altered physical signs in the lung. Since there was neither collapse nor edema, there was nothing to alter the percussion note or change the fremitus or breath sounds.

The thrombosis undoubtedly explains the cyanosis, for which no adequate explanation had been found during life, but which was thought to point to a lesion in the pulmonary circuit. Deep cyanosis is characteristic of other pulmonary artery diseases, so-

called Ayerza's disease, for example, and is probably to be explained on the basis of diminished aerating surface to which blood can be exposed with consequent greater reduction of hemoglobin in passage through the lungs.

To what extent the thrombus contributed to the heart failure is impossible to say. The patient was entitled to die of congestive heart failure without it. Our guess, however, is that it probably importantly accelerated the failure. The hypertrophy of the right ventricle would substantiate this view. The thrombus could do this both by increasing the anoxemia, as well as by producing pulmonary hypertension by diminishing the total diameter of the pulmonary arterial tree. This seems to have happened in the patient of Barnes and Yater and also in that of Jump and Baumann.

CONCLUSIONS

Total thrombotic occlusion of a main branch of the pulmonary artery may occur without damage to the lung provided it develops slowly enough to allow for the development of collateral circulation through the bronchial system.

Such a lesion may produce no local signs in the lungs but the presence of cyanosis and right-sided heart failure without other obvious cause may suggest its presence.

The Therapeutic Use of Oxygen in Heart Disease*

By ALVAN L. BARACH, M D, New York City

INTRODUCTION

OXYGEN is the fundamental requirement for the transformation of energy in the body. A normal supply of oxygen to the tissues in an individual living at sea level atmospheric pressure is maintained essentially by intact respiratory and cardiac systems. Although the metabolism is not altered by an increase in the oxygen supply (Voit,¹ Pfluger,² and Benedict and Higgins,³) reduction in the normal amount of oxygen furnished to the tissues results in profound alterations in the chemical processes of the body. A state of oxygen-want or anoxemia may be produced by a diminished concentration of oxygen in the outside air or through an impairment of the respiratory or cardiac systems.

HISTORY

The direct effects of oxygen-want have been observed by many physiologists, either through studies at high altitude or through experiments in chambers in which the partial pressure of oxygen is lowered. Headache, nausea, and vomiting, irrational states and mental depression are common symptoms. The pulse is invariably elevated. The respiration is frequently periodic in char-

acter, changing to rapid and shallow breathing. In abrupt and severe want of oxygen, delirium, coma and cardiac failure occur (Haldane,⁴ Bancroft⁵).

Von Terray⁶ found, as a result of the production of severe anoxemia, an increase in the excretion of carbon dioxide, increased elimination of nitrogen and a marked production of organic acids. Schneider, Truesdell and Clarke⁷ also observed an increased elimination of carbon dioxide in periods of anoxemia which was immediately reduced by the inhalation of oxygen. Krogh⁸ reported a decrease in the rate of oxidation when the oxygen supply to the tissues was diminished beyond a certain point, namely, when the oxygen pressure in the inspired air fell below 83 mm, or atmospheric pressure of 410 mm.

The rôle of oxygen-want in the production of the symptoms of heart disease has not been clearly understood. Previous studies bearing on this factor will now be referred to. Means and Newburgh⁹ found a diminished oxygen saturation of the venous blood in cases of cardiac decompensation. These results were confirmed and amplified by Lundsgaard.¹⁰ Harrop¹¹ showed that a diminished arterial oxygen saturation was present in cases of cardiac insufficiency. Barach and Woodwell¹² administered 40 to 60 per cent oxygen over short periods of time and observed that an increase in both the arterial and venous oxygen saturations occurred. When the arterial anoxemia was due to passive congestion and edema of the bases of the lungs, oxygen treatment regularly raised the arterial saturation to the normal level. The elevation of the venous saturation seemed largely dependent upon the increase of the arterial oxygen saturation. Diminution of

*Presented at the Baltimore Meeting of the American College of Physicians, March 23, 1931. From the Department of Medicine, College of Physicians and Surgeons, Columbia University and the Presbyterian Hospital, New York City.

cyanosis and slowing of the pulse were the outstanding objective changes. There was in some cases an increase in carbon dioxide content of the arterial and venous blood. In two cases of right bundle branch block, a decreased notching and a diminished height of the R wave were present during the inhalation of oxygen.

Beddard and Pembrey¹³ found the carbon dioxide of the alveolar air reduced in cases of cardiac decompensation. This was confirmed by Fitzgerald¹⁴ and later by Porges, Leimdorfer and Markovici¹⁵ who observed that the alveolar carbon dioxide was low in cases of cardiac disease in whom dyspnea was present and normal in those without dyspnea. Peabody¹⁶ observed, in some cases of cardiac disease, that a lowered tension of the alveolar carbon dioxide was present during the dyspneic period followed by a rise when compensation was regained.

The relation between the alveolar and arterial carbon dioxide tensions was studied by Peters and Barr¹⁷ who found that the alveolar values were decidedly lower than the arterial in advanced decompensation. The same observation was noted by Campbell and Poulton¹⁸.

The carbon dioxide dissociation curves of the blood were found by Peters and Barr¹⁷ to be at normal levels in mild or moderate cardiac insufficiency but definitely reduced in certain cases of advanced heart failure, particularly those with marked cyanosis.

The H-ion concentration of the arterial blood in cardiac disease may be altered by associated pulmonary or renal disease, administration of morphine and other complicating factors. In general it has been reported to be within normal limits in mild or moderate degrees of heart failure and definitely acid in extreme failure, with return to normal when compensation was restored (Peters and Barr¹⁷). Instances of an alkaline pH in a few cases of cardiac dyspnea have been reported by Campbell and Poulton¹⁹.

In 1908 Beddard and Pembrey²⁰ observed that the inhalation of oxygen resulted in a decreased pulmonary ventilation in a patient with cardiac insufficiency. This finding was later reported by Campbell, Hunt and Poul-

ton²¹ who observed also a corresponding increase in the carbon dioxide concentration of the expired air. It is interesting to note that in normal animals living in high oxygen atmospheres, J. A. Campbell²² noted an increase in tissue tensions of both oxygen and carbon dioxide.

Recently, Baker²³ reported a case of bundle branch block in which inhalation of oxygen resulted in a disappearance of the aberrant ventricular complexes and a striking improvement in intraventricular conductivity.

RESULTS

In this communication we wish to present the results of studies of the effects of oxygen therapy in various types of heart disease done in collaboration with D. W. Richards²⁴ and R. L. Levy²⁵ at the Presbyterian Hospital, New York, during the past three years. Since one of the handicaps in the previous studies of the therapeutic use of oxygen has been that it was generally administered ineffectively, we shall note briefly the methods of oxygen therapy which we employed. The Barach oxygen chamber²⁶ and oxygen tent²⁷ were employed to administer 40 to 50 per cent oxygen. In the oxygen chamber a constant temperature and humidity regulation was achieved and in the oxygen tent the temperature was kept below 70 degrees and the humidity below 50 per cent. In the treatment of patients with dyspnea it is of the greatest importance, not only to be accurate in the determination of the oxygen concentration employed but also to provide a comfortable atmospheric environment. Oxygen therapy will not be successful if types of apparatus are used which do not effectively remove the heat and moisture eliminated by the patient, in addition to furnishing 40 to 50 per

RESULTS

In this communication we wish to present the results of studies of the effects of oxygen therapy in various types of heart disease done in collaboration with D. W. Richards²⁴ and R. L. Levy²⁵ at the Presbyterian Hospital, New York, during the past three years. Since one of the handicaps in the previous studies of the therapeutic use of oxygen has been that it was generally administered ineffectively, we shall note briefly the methods of oxygen therapy which we employed. The Barach oxygen chamber²⁶ and oxygen tent²⁷ were employed to administer 40 to 50 per cent oxygen. In the oxygen chamber a constant temperature and humidity regulation was achieved and in the oxygen tent the temperature was kept below 70 degrees and the humidity below 50 per cent. In the treatment of patients with dyspnea it is of the greatest importance, not only to be accurate in the determination of the oxygen concentration employed but also to provide a comfortable atmospheric environment. Oxygen therapy will not be successful if types of apparatus are used which do not effectively remove the heat and moisture eliminated by the patient, in addition to furnishing 40 to 50 per

cent oxygen in the inspired air. In some cases when lower oxygen concentrations were employed, the nasal catheter was used to furnish 30 to 35 per cent oxygen as described in a previous article.⁴

We wish to report upon the therapeutic use of oxygen in twenty patients who may be classified under the following four headings:

- 1 Congestive heart failure due to primary cardiac disease
- 2 Cardiac insufficiency developing as a sequel to chronic pulmonary disease
- 3 Acute coronary thrombosis
- 4 Coronary arteriosclerosis with chronic cardiac pain

1 CONGESTIVE HEART FAILURE DUE TO PRIMARY CARDIAC DISEASE*

The effects of living for two to five weeks in an atmosphere containing 45 per cent oxygen were studied in eight patients with congestive heart failure by Dr. Richards and myself. Although there was a considerable variation in their pathology, from a clinical standpoint they were all cases of advanced cardiac insufficiency. All were cyanotic, suffered from dyspnea at rest, and all except one had marked orthopnea and generalized edema. The patients were first observed from one to eight weeks on the ward on routine treatment. When there appeared to be no further clinical improvement or when the patient was definitely losing weight, transfer was made to the

oxygen room where the patient inspired 45 per cent oxygen.

In four patients who suffered from degenerative heart disease characterized by intense dyspnea and orthopnea, marked cyanosis and peripheral edema, the major effects of residence in an atmosphere of 45 per cent oxygen were:

(1) Marked subjective improvement, decrease of cyanosis, relief of dyspnea, orthopnea and cough, beginning generally within three hours after their entrance into a high oxygen atmosphere.

(2) Increase of urinary output and disappearance of edema, of gradual onset and usually not reaching its maximum for three to five days. In three patients a return to normal atmospheric oxygen resulted in a decreased urinary output and a return of edema. Raising the oxygen concentration again brought about a second diuresis. In two, this sequence was obtained both by transferring the patient from the oxygen room to the ward and by lowering and raising the oxygen within the chamber without removing the patient.

(3) Increased arterial oxygen saturation.

(4) Sharp rise in carbon dioxide content of arterial blood, and in carbon dioxide curve level, in high oxygen.

(5) Decreased pulmonary ventilation.

(6) Lowered pulse rate.

(7) In the case of one patient other measurements showed, (a) slight increase in cardiac output, (b) sharp fall in blood lactic acid from 220 mg. to a normal value of 7 mg.

* This study was reported by Barach, A. L., and Richards, D. W. *Annals of the New York Academy of Medicine*, Vol. 45, No. 1, 1945.

In these cases, all of whom may be said to have improved in 45 per cent oxygen, there were other changes which occurred, although not constantly lowered respiratory rate, lowered body temperature, decreased basal metabolism, slightly higher arterial pH, increase in vital capacity and fall in red blood count and hemoglobin.

Two other cases had advanced and active rheumatic heart disease, with cyanosis, generalized passive congestion, edema, and irregular fever. Subjectively, they were more comfortable and less dyspneic in high oxygen, their cyanosis was somewhat improved and comparative measurements on one case showed an increase in arterial oxygen saturation from 84 to 93 per cent. There was in each case a moderate rise in carbon dioxide curve level. Little change, however, occurred in the edema, and there was no tendency to diuresis. However, one patient was removed rather abruptly from 45 per cent oxygen to the ward, where she rapidly went into collapse, with renal suppression for 20 hours, low blood pressure, and profound cyanosis. Her arterial oxygen saturation again went down to 84 per cent (this measurement was taken when patient was receiving four liters of oxygen per minute by nasal catheter), carbon dioxide dropped to the remarkably low value of 26.4 volumes per cent, and arterial pH fell from 7.44 to 7.36. After return to 45 per cent in the chamber she recovered quickly to her former state. During the next 24 hours she passed 1000 cc of urine. These two patients both showed lowered pulse rate while in high oxygen.

Finally, two patients showed practically no reaction whatever to the increase in atmospheric oxygen. One was a man of 54, with long-standing mitral stenosis, great cardiac enlargement, enlargement of the liver, but no edema and no orthopnea. Clinically, he was moderately cyanotic, but this was evidently of venous origin as his arterial blood when he was in the ward was 91 per cent saturated with oxygen or better. The development of a mild rhinitis and bronchitis with a transient lowering of the carbon dioxide curve, and of the vital capacity, seemed to be the only change while he was in the oxygen room. Subjectively, he was no better.

The second was a girl of 13 with congenital heart disease, later shown by autopsy to be the tetralogy of Fallot, combined with a patent ductus arteriosus. The case is being reported by Dr. Richards²⁹ in further detail elsewhere. It is sufficient to note here that her arterial oxygen saturation, about 60 per cent, was increased only slightly, to 65 per cent, in high oxygen, that there was no change in her carbon dioxide or in her urinary output, that her pulmonary blood flow was practically unaltered, and that subjectively she was not improved. She did not have any edema at any time. She was not in the oxygen room long enough to rule out the possibility of a change in urinary output relative to intake.

II. CARDIAC INSUFFICIENCY DEVELOPING AS A SEQUEL TO CHRONIC PULMONARY DISEASE

The effects of oxygen therapy were studied in five cases of cardiac insufficiency due to previous chronic

cent oxygen in the inspired air. In some cases when lower oxygen concentrations were employed, the nasal catheter was used to furnish 30 to 35 per cent oxygen as described in a previous article²⁸

We wish to report upon the therapeutic use of oxygen in twenty patients who may be classified under the following four headings

One was a man of 54, with long-standing mitral stenosis, great cardiac enlargement, enlargement of the liver, but no edema and no orthopnea. Clinically, he was moderately cyanotic, but this was evidently of venous origin as his arterial blood when he was in the ward was 91 per cent saturated with oxygen or better. The development of a mild rhinitis and bronchitis with a transient lowering of the carbon dioxide curve, and of the vital capacity, seemed to be the only change while he was in the oxygen room. Subjectively, he was no better.

The second was a girl of 13 with congenital heart disease, later shown by autopsy to be the tetralogy of Fallot, combined with a patent ductus arteriosus. The case is being reported by Dr. Richards²⁹ in further detail elsewhere. It is sufficient to note here that her arterial oxygen saturation, about 60 per cent, was increased only slightly, to 65 per cent, in high oxygen, that there was no change in her carbon dioxide or in her urinary output, that her pulmonary blood flow was practically unaltered, and that subjectively she was not improved. She did not have any edema at any time. She was not in the oxygen room long enough to rule out the possibility of a change in urinary output relative to intake.

II CARDIAC INSUFFICIENCY DEVELOPING AS A SEQUEL TO CHRONIC PULMONARY DISEASE

The effects of oxygen therapy were studied in five cases of cardiac insufficiency due to previous chronic

pulmonary disease two cases of pulmonary tuberculosis, two cases of fibrosis of the lung and one case of emphysema. In these patients, treatment with oxygen was carried on during a period of two to seven months. The tuberculous patients had active tuberculosis with extensive pathology in their lungs. They were both dyspneic at rest, cyanotic, with an elevated temperature and pulse rate. In each instance, residence in the oxygen chamber was followed by increase in comfort, lessened dyspnea, and other evidences of clinical improvement such as increased appetite and lowered pulse rate. In one of them the symptoms of respiratory failure were extreme, and the inhalation of 45 per cent oxygen appeared to prolong life until the acute processes had somewhat subsided. No effect, however, was noted on the progress of the tuberculous lesion itself. In one who had been in the oxygen chamber for two and one-half months a marked rise in arterial carbon dioxide was associated with the increase in the arterial oxygen saturation.

The first patient with fibrosis of the lung was a woman of forty-nine years of age who suffered from progressively extreme dyspnea, marked cyanosis, and paroxysmal coughing for two years. Her respirations were 60 per minute, very shallow, pulse rate 110 without fever. She was kept in an oxygen chamber for six months. During the first month her respirations declined to as low as 28 per minute, pulse to 80 with relief of dyspnea and complete disappearance of coughing. The fibrosis of the lung, however, steadily advanced and it became necessary to give her increasing concentra-

tions of oxygen, from 40 per cent at the start to 55 per cent at the termination of her illness. She died as a result of cerebral thrombosis. A week before her death the arterial oxygen saturation was 89 per cent and the arterial carbon dioxide content had reached the extraordinary figure of 132.1 volumes per cent. (In the cases of congestive heart failure relieved in high oxygen, the arterial carbon dioxide content was elevated from a range of 35 to 40 volumes per cent before oxygen treatment to 45 to 70 volumes per cent after oxygen treatment.) In the second case of fibrosis of the lung which was associated with marked cardiac insufficiency the arterial carbon dioxide content rose from 35.4 volumes per cent to 69.9 volumes per cent and subsequently as improvement in pulmonary function occurred dropped to 48.9 volumes per cent. This patient for a period of five months appeared unable to live without oxygen. Whenever oxygen was discontinued he became dyspneic, cyanotic, and began to accumulate edema fluid. However, at the end of five months oxygen therapy was stopped without recurrence of symptoms of cardiac or respiratory failure. For eight months he was able to go about on restricted activity without distress. At the end of this time slight symptoms of cardiac failure became evident and the patient was put on nasal oxygen for a varying number of hours (2 to 4) during the day.

The patient with emphysema was a man of fifty who suffered from progressive impairment of pulmonary function for a period of seven years. At the time he was seen cardiac insufficiency was so marked as to presage a fatal outcome. He was intensely

cyanotic and dyspneic, gasping at every breath, with a rapid pulse of poor quality. He was treated in an oxygen tent with 50 per cent oxygen for ten days with disappearance of dyspnea and cyanosis. His pulse gradually improved in volume and dropped from 100 to 76. After continuous nasal oxygen at 40 liters a minute through a catheter for one month, nasal catheter treatment was continued for six to eight hours daily, for the following three months. After this period he was able to resume ambulatory activity without oxygen.

III ACUTE CORONARY THROMBOSIS

Dr. Levy and I studied the effects of the administration of 45 per cent oxygen by means of the oxygen tent in four patients suffering from coronary thrombosis. All were critically ill. The following observations were made in these cases:

- 1 Subjective improvement occurred in from one to three hours after the administration of oxygen was begun. This manifested itself chiefly by relief of respiratory embarrassment and restlessness.

- 2 Cyanosis was diminished or abolished.

- 3 The respiratory rate was slowed and Cheyne-Stokes breathing, if present, tended to disappear.

- 4 The heart rate became slower. The heart sounds grew stronger and the volume of the pulse improved.

- 5 Removal of the oxygen tent before satisfactory readjustment of circulatory conditions had taken place resulted in a recurrence of the symptoms and signs just enumerated.

In sudden thrombotic closure of a branch of the coronary artery there results an abrupt interference with the blood supply of the heart which induces an initial state of shock. The degree of functional disturbance that follows depends on the caliber and location of the occluded vessel, as well as on the distribution and anastomoses of the coronary system in the affected individual. If the resulting area of myocardial infarction is large, signs and symptoms of congestive heart failure may ensue. The cardiac action becomes weak, rapid and often irregular. The blood pressure falls sharply and remains at a relatively low level. Cyanosis appears, and moist râles are heard at the bases of the lungs. Respiration is accelerated and difficult. The picture is one of acute oxygen-want due to myocardial insufficiency.

Employment of oxygen therapy (preferably in a concentration of from 45 to 50 per cent) may aid in maintaining an adequate circulation until the heart has had an opportunity to recover from its acute functional disturbance. Obviously, the cardiac injury may be so severe that recovery is impossible. But in some instances effective use of oxygen may be responsible for the saving of life.

The responses of the cases studied allow the conviction that anoxemia and its treatment may play a crucial rôle in determining the outcome after coronary thrombosis.

IV CORONARY ARTERIOSCLEROSIS WITH CHRONIC CARDIAC PAIN

I have recently studied three cases of coronary arteriosclerosis with chronic cardiac pain in men in the fifth

and sixth decades of life. All these patients had one to five attacks of cardiac pain daily at rest in bed before treatment with oxygen. They were treated by residence in the oxygen chamber with 50 per cent oxygen for a period of two weeks. In the first, which was the most severe, the attacks gradually decreased in number and severity, but promptly recurred when the patient was removed from the chamber. His condition was at all times exceedingly grave and he died three weeks after removal from the oxygen chamber. In the second case the attacks of pain gradually disappeared. After removal from the oxygen room the pains recurred to a slight extent but permitted the patient to return home. During the following six months he has been markedly improved over his previous condition, having only a comparatively small number of attacks of mild pain, i.e., two to three attacks a month, none of them requiring more than rest and nitroglycerin.

The third patient was less severely affected than the others, averaging one attack of pain daily at rest in bed in the hospital before admission to the chamber. During ten days residence in 45 per cent oxygen he had one attack of pain, and felt extremely well. For six weeks after he was able to resume restricted activity without pain. At that time, however, pain recurred waking him up during the night. He was placed on nasal oxygen, 40 liters per minute for eight hours a day for six weeks and since that time, a period of four months, he has had only occasionally mild pain on activity and is not awakened at night by cardiac pain.

DISCUSSION

The improvement which was evident in the cases of acute coronary thrombosis after inhalation of 45 to 50 per cent oxygen indicates the importance of the factor of oxygen-want in this condition. After coronary closure there is first a pronounced anoxemia of the heart muscle, followed by anoxemia in the venous blood as a result of the impaired heart action and, very soon after, an arterial anoxemia due to the development of passive congestion and edema of the lungs. The inhalation of 45 to 50 per cent oxygen tends to remove the arterial anoxemia and prolong life until the heart is able to compensate, if it is possible to do so, for its acute disturbance in function. The prompt collapse which follows withdrawal of oxygen before the heart muscle has adapted itself to the closure makes manifest the significance of arterial anoxemia in the symptomatology of the disease.

The problem of interpreting the origin of cardiac pain is complicated by the fact that no afferent nerve fibres are to be found in the heart muscle or its blood vessels. The possibility is present that supposedly efferent sympathetic nerves in the heart muscle may carry afferent impulses. Wiggers¹¹ observes in a recent review that although "Sir Clifford Allbutt maintained to the end of his life that cardiac angina could arise only from stimulation of the nerve fibres terminating in the outer coats of the aorta, a great deal of clinical and even a little experimental evidence exists that anoxemia of the heart muscle—regardless of whether it is produced by cor-

onary embolism, thrombosis or sclerosis —is capable of inaugurating serious attacks of cardiac pain" That local anoxemia of the heart muscle may produce pain is certainly suggested by the relief of pain in the three cases of coronary arteriosclerosis who were treated in the oxygen room

Although we cannot entirely explain the mechanism by which relief of pain occurs in cases of coronary arteriosclerosis without cyanosis or evident anoxemia, we have obtained some knowledge that bears on the problem. In the first place, the inhalation of 50 per cent oxygen in normal men we have found capable of raising the arterial oxygen saturation from 95 to 99 per cent. In one of the cases of coronary arteriosclerosis which we measured, the arterial oxygen saturation was raised from 94 to 99 per cent. Although this represents a small increase in per cent saturation, it indicates a very considerable rise in the tension or partial pressure of oxygen available to the tissues (because of the shape of the oxygen dissociation curve), and provides therefore a possible explanation for relief of local anoxemia in the heart muscle. The inhalation of high concentrations of oxygen causes the normal heart to beat at a slower rate,³⁰ and affects more markedly the heart in cardiac insufficiency,^{12,24} which suggests a lessened strain due to a greater oxygen supply.

The most interesting and striking effects of oxygen therapy in the cases of cardiac insufficiency, both those due to local disease of the heart itself and those in which heart failure appeared to be secondary to primary pulmonary

disease are (1) Relief of dyspnea and orthopnea, (2) elevation of the arterial carbon dioxide content and of the level of the carbon dioxide dissociation curves, and (3) diuresis.

1. The relief of dyspnea which frequently manifests itself within several hours after removal to an oxygen-enriched atmosphere indicates that oxygen-want plays a decisive rôle in the production of cardiac dyspnea. We may briefly review at this point some of the known factors involved in the production of shortness of breath in cardiac insufficiency.

Passive congestion and edema in the lungs was noted by von Basch³² as resulting in a stiffening of the lung with consequent impairment of the expansile capacity of the lungs, or vital capacity. Siebeck³³ also found that the lung expands unequally in cardiac insufficiency and thus makes for an imperfect mixture of the gases in the lung, with resultant impairment of normal diffusion of oxygen. In addition to these difficulties in moving the lung, there must also be a decreased diffusion capacity of the swollen alveolar membrane for respired gases especially oxygen. The end result of pulmonary dysfunction is insufficient oxygen saturation of the arterial blood. This involves all the tissues in the consequences of anoxemia, many of which have been noted in the introduction. An additional one may be commented upon at this point, namely lactic acid accumulation (Araki³⁴) (MacLeod³⁵). An accumulation of lactic acid is of particular interest with reference to the respiratory center. At the present time the most satisfactory explanation of the respiratory stimulus

is that it is governed by the acidity of the tissue of the respiratory center (Douglas and Haldane³⁶), (Winterstein³⁷), (Gesell³⁸)

When in our cases the clearing of arterial anoxemia resulted from the inhalation of 45 to 50 per cent oxygen, dyspnea was relieved and gradually disappeared. It is evident (1) that the difficulties in oxygen absorption resulting from lung stiffening, decreased vital capacity and swollen alveolar membranes were overcome, and (2) that the increased oxygen saturation of the pulmonary blood tends to diminish tissue acid accumulation. In the one case measured, the blood lactic acid rapidly returned to normal following the inhalation of oxygen. That the respiratory stimulus was thereby decreased is evidenced by the lowered pulmonary ventilation and that there was some diminution in general tissue acidity was suggested by the small but constant lowering of arterial H-ion concentration which we observed.

The difficulty of eliminating carbon dioxide has also been stressed as an important factor in the causation of cardiac dyspnea, which brings us to the second result of oxygen therapy to be discussed.

2 The marked rise in carbon dioxide content of the arterial blood was constantly associated with (1) clinical improvement, (2) increased arterial oxygen saturation, and (3) impairment of pulmonary function in respect to the absorption of oxygen.

If the inhalation of oxygen-enriched air makes possible a lower pulmonary ventilation it is obvious that an increase in blood carbon dioxide levels

and hence in alveolar air will permit the elimination of a greater amount of carbon dioxide with a lower pulmonary ventilation. In the cases of congestive failure due to primary cardiac disease the arterial carbon dioxide content was elevated from a range of 35 to 40 volumes per cent to 45 to 70 volumes per cent, after oxygen treatment. This increase in the carbon dioxide levels in the blood did not, however, represent a carbon dioxide acidosis due to deficient elimination of carbon dioxide, since the H-ion concentration of the blood was never more acid but on the contrary, tended to be slightly less acid when the carbon dioxide became elevated. It is therefore evident that carbon dioxide diffuses through the lungs in higher concentrations when anoxemia and its consequences are relieved. This fact necessitates an alteration in the conception of previous investigators concerning the rôle of carbon dioxide in the causation of cardiac dyspnea.

Wiggers¹¹ remarks in a recent review of the physiology of cardiac dyspnea that "Neither an excess of carbon dioxide, as in exercise, nor the existence of a fixed acidosis is separately responsible for the dyspnea. But a moderate grade of fixed acidosis combined with pulmonary congestion which prevents the compensatory elimination of carbon dioxide might easily produce augmented breathing in heart disease. In the light of this conception, also, it appears to be a basic fact that impairment of the pulmonary circulation is the ultimate cause that prevents the free compensatory elimination of carbon dioxide."

Our studies, however, indicate that lack of oxygen plays the primary rôle in the production of cardiac dyspnea. Passive congestion of the alveolar membranes of the lung and the associated decreased vital capacity impair, first of all, the diffusion of oxygen into the pulmonary veins, resulting in arterial anoxemia and the consequences of oxygen-want in the tissues, such as accumulation of lactic acid. When the anoxemia is relieved, there is a constant and marked rise in the carbon dioxide concentration of the blood with an *even greater elimination* of carbon dioxide per breath through the congested lung. Thus, in one of the cases of congestive failure, the carbon dioxide content of the arterial blood rose from 38.4 to 69.9 volumes per cent in four days. It appears, therefore, likely that the elevation in carbon dioxide level in the blood is an adaptive change which is readily accomplished if sufficient oxygen is supplied to maintain normal metabolic activity. Also, lactic acid accumulation disappears when anoxemia is relieved. It seems probable that base to retain carbon dioxide is in part derived from the blood lactates in this manner. A decrease in pulmonary ventilation follows with a lessened sense of pulmonary effort and therefore relief of dyspnea.

To summarize, then, cardiac dyspnea was relieved (1) by the provision of an adequate oxygen supply to the tissues, (2) by the development of a mechanism of eliminating carbon dioxide by increasing the concentration in the blood, and (3) by the oxidation of an excessive accumulation of lactic acid in the blood.

We may consider now the general factor involved in the increase in blood carbon dioxide which follows oxygen treatment in the cases of cardiac failure as well as in the cases of chronic pulmonary disease. This appears to be the extent of impairment of pulmonary function in respect to the absorption of oxygen. In the patient with fibrosis of the lung in whom a progressive impairment of the function of the lung took place so that 55 per cent oxygen became necessary to support life, the blood carbon dioxide reached 132.1 volumes per cent. It would appear that this extraordinary high concentration of carbon dioxide in the alveolar air represented a mechanism capable of eliminating carbon dioxide in the presence of an extreme diminution of lung function. In the second patient with fibrosis of the lung and cardiac insufficiency, the carbon dioxide in the arterial blood rose from 38.4 to 69.9 after four days' oxygen treatment, and then, as the patient improved, dropped to 48.9 volume per cent, even though he was still breathing an oxygen-enriched atmosphere. Thus, when the function of the lung, if severely impaired, was relieved by the inhalation of oxygen, the carbon dioxide concentration in the blood and in the alveolar air became elevated, as an adaptive reaction noted above. But when the pulmonary function improved in respect to the absorption of oxygen, the carbon dioxide concentration in the blood and alveolar air diminished.

Although the carbon dioxide in the blood declines after clinical improvement has taken place whether the patient is breathing oxygen or air, a slight increase in blood carbon dioxide

may still persist in a high oxygen atmosphere. It has been noted in animals kept in oxygen-enriched atmospheres that an increase in carbon dioxide tension in the tissues occurs (Campbell²²). The significance of the elevation in carbon dioxide in normal animals exposed to high oxygen is not clear. As far as our purposes are concerned, the rise in carbon dioxide following oxygen treatment in patients suffering from dyspnea appears to be an adaptive mechanism for eliminating carbon dioxide, accompanied by a decreased pulmonary ventilation which is made possible only by the relief of anoxemia and its consequences.

3 The diuresis and disappearance of edema was a marked feature of four of our cases. The physiologic explanation of cardiac edema is itself by no means clear, but three factors have been described: (1) edema of the dependent parts due to stasis and physical filtration, (2) impairment of renal function due to congested glomerular membranes, and (3) altered permeability of capillaries due to anoxemia⁴¹. Oxygen therapy resulted in an improved state of the circulation which would tend to remove the edema due to stasis as well as relieve the passively congested glomerular membranes. In so far as the tissue cells of the body are altered in their permeability due to anoxemia, an increased supply of oxygen would likewise be beneficial. Other alterations in tissue water balance may also be implicated concerning which our data give no information.

I am conscious that this discussion of the therapeutic use of oxygen in heart disease displays many large gaps in our knowledge. It is our hope,

however, that these observations will stimulate further studies in which effective and comfortable methods of administering oxygen will fulfil the prophecy of Priestley shortly after he had discovered oxygen 157 years ago.

"My reader will not wonder", says Priestley,⁴² "that, after having ascertained the superior goodness of dephlogisticated air (that is, oxygen), by mice living in it and by the other tests above mentioned, I should have the curiosity to taste it myself. I have gratified that curiosity by breathing it, drawing it through a glass syphon, and by this means I reduced a large jar full of it to the standard of common air. The feeling of it to my lungs was not different from common air, but I fancied that my breath felt peculiarly light and easy for some time to come. Who can tell but that in time this pure air may become a fashionable article in luxury? Hitherto only two mice and myself have had the privilege of breathing it."

SUMMARY

The therapeutic use of oxygen was studied in eight patients with congestive heart failure due to primary cardiac disease, in five cases of cardiac insufficiency developing as a sequel to chronic pulmonary diseases, in four cases of acute coronary thrombosis and in three cases of coronary arteriosclerosis with chronic cardiac pain.

In the cases of congestive heart failure the most striking effects observed were (1) relief of dyspnea and orthopnea, (2) diuresis and disappearance of edema, and (3) a marked rise in the carbon dioxide content of the arterial blood. Other observations noted were relief of cyanosis, in

creased arterial oxygen saturation, decreased pulmonary ventilation, lowered pulse rate and decrease in blood lactic acid

In the cases of acute coronary thrombosis life appeared to be prolonged by the inhalation of an oxygen-enriched atmosphere until the heart was able to recover from its acute functional disturbance. The cases of coronary arteriosclerosis with chronic cardiac pain were relieved by residence in a high oxygen atmosphere

These results indicate that oxygen-want plays the primary rôle in the production of many forms of cardiac dyspnea. The increase in carbon dioxide content of the arterial blood occurs as an adaptative change which facilitates the elimination of carbon dioxide

The clinical improvement which patients suffering from the various forms of heart failure experience suggests a new employment of oxygen therapy by effective methods in these conditions

The Reaction to Nitrites in the Anginal Syndrome and Arterial Hypertension*

By ALEX M. BURGESS, M.D., F.A.C.P., *Providence, R. I.*

SINCE the introduction of the use of amyl nitrite by Sir Lauder Brunton in 1867 nothing has been found to excel the nitrites for the relief of the pain in angina pectoris. Although the pharmacology of the members of this group has been exhaustively studied the question as to the mode of their action in anginal pain has never been definitely settled. This is due partly to the fact that the cause of the pain has not been thoroughly understood. Furthermore, because of their known action on the walls of the peripheral arterioles resulting in a lowering of blood pressure, the nitrites have been used in attempts to cause either temporary or permanent lowering of the pressure in patients suffering from arterial hypertension and are therefore of interest to the clinician. The relaxability of the walls of the arterioles as measured by the drop in diastolic pressure after the inhalation of amyl nitrite has also been studied in an attempt to estimate the prognosis in these cases¹. It has seemed worth while, therefore, to make a series of simple clinical tests by means of repeated blood pressure esti-

mations of the reaction which the rapidly acting drugs, amyl nitrite and nitroglycerine produce in three types of people—the normal, those with arterial hypertension and those who are suffering from attacks of the so-called “ambulatory” angina pectoris.

No attempt will be made to enter into an exhaustive discussion of the pharmacology of the nitrite group. The familiar text book description mentions the flushing of the face, headache, and tachycardia after the inhalation of amyl nitrite, and the rapid fall in blood pressure due to a direct action on the smooth muscle cells of the walls of the arterioles and veins. A similar but less rapid effect is attributed to nitroglycerine. Anyone who has tested the amyl nitrite on himself can bear witness to the very unpleasant nature of the subjective symptoms produced in a normal person. That the tachycardia is due to vagus action has been shown, as it does not occur in experimental animals if the nerve has been severed. It has been amply demonstrated that the fall in pressure is due to a direct action on the vessel walls.

The statement is common that in hypertension generally the action of amyl nitrite and nitroglycerine is to

*Presented at the Baltimore Meeting of the American College of Physicians, March 24, 1931

produce a sharp and temporary fall in blood pressure² although no detailed studies of this action on systolic and diastolic pressure are available. Stieglitz³ has recently emphasized the importance of a fall in diastolic pressure in these cases after the inhalation of amyl nitrite as indicating that the peripheral arterioles have not yet reached an advanced state of sclerosis and therefore that the prognosis may still be favorable. He recommends that the pressure be taken at the height of the symptoms; flushing, tachycardia, etc., and that the proportion of the distance that the diastolic has fallen toward 90 mm. be taken as the indication of arteriolar relaxability.

The action of the nitrites on the cerebral circulation is of especial interest to those who have attempted to relieve headache in cases of arterial hypertension by their use. It has been clearly shown⁴ that the pial vessels are dilated by these drugs and that intracranial pressure is increased⁵. The writer has seen a severe headache in a patient with marked arterial hypertension made almost intolerable by a dose of 1/100 grain of nitroglycerine which, by the way, had no appreciable effect on the blood pressure (see Chart 4).

The effect of the nitrites on the pulmonary circulation is apparently the opposite of that on the general circulation. Isolated strips of pulmonary artery have been noted to contract when in contact with the nitrites⁶ and a rise in pulmonary pressure has been demonstrated after their use.

As regards the coronary arteries

the statement is made that they also are dilated as are other peripheral arteries. Dilation of isolated rings of coronary artery⁷ and increased outflow from the coronary veins have been shown to be the result of nitrite action by some observers,⁸ while others have been unable to produce experimentally, any definite evidence of such action⁹. Perhaps, however, the best demonstration of the effect on the coronaries is that by Smith¹⁰ who showed in dogs' hearts in which artificial infarction had been produced by ligation of the coronary branches an actual decrease in the cyanosis of the infarcted areas due to increased collateral circulation following the intraventricular injection of 1/200 grain of nitroglycerine.

The demonstration of an increase in coronary flow by the nitrites is of great importance in upholding the view that the pain in angina pectoris is caused by ischemia of the heart muscle, so ably championed by Keefer and Resnik¹¹. These investigators are, however, very sceptical as to the likelihood of "coronary spasm" as a usual origin of the pain. Whatever may be the cause of the ischemia, it is safe to say that if this ischemia is the cause of the pain, dilation of the coronary arteries seems a reasonable mechanism of its relief. If, on the other hand, a tendency to stasis in the first part of aorta and in the coronaries is the cause of the pain, as believed by May¹², then, as he says, the dropping of the diastolic pressure by the nitrites is a reasonable mechanism for its relief. The following studies do, it is believed, throw some light on this question.

CHART 3 Arterial hypertension. Note absence of fall in diastolic pressure after amyl nitrite in spite of normal retinal vessels and kidneys

CHART 1. Arterial hypertension, severe, with marked retinal edema. Note increase in headache following nitroglycerine without fall in blood pressure.

THE REACTION IN THE NORMAL HUMAN BEING

A few preliminary tests were made on normal persons. As Charts 1 and 2 demonstrate, the action was found to be as follows: (1) After nitroglycerine (either 1/100 or 1/50 grain dissolved in the mouth or gr 1/100 subcutaneously) no immediate fall in blood pressure was noticed although there was a general tendency for the systolic pressure to fall during the next few minutes. Such a general decrease is also often noted in normal people with rest alone. No fall in diastolic pressure was noted. (2) After amyl nitrite an abrupt fall occurred in 30 seconds in both systolic and diastolic pressure. This was followed by a quick compensatory rise in both systolic and diastolic pressure sometimes to points above the original readings. After two minutes the pressure was not much different from that observed at the start and no further effect was noted except in some instances a slight tendency downward on the part of the systolic pressure. (See Chart 2.)

THE REACTION IN ARTERIAL HYPERTENSION

(1) Following the administration of nitroglycerine gr 1/100 or 1/50 by mouth the majority of the sixteen patients studied by this method showed no constant effect on either systolic or diastolic pressure although a fall occurred in some instances. As a comparable fall is often noted¹³ with rest alone it is probable that in these patients the lowering of pressure was due to the rest rather than to the drug. (Charts 3, 4, 5 and 9.) (2)

After amyl nitrite in the twelve patients investigated, the same sudden drop was seen in systolic pressure as was noted in normals, but the subsequent rise did not as a rule reach the original height. The diastolic pressure fell markedly in some and not at all in others. It is worth noting that the fall in pressure after amyl nitrite is so rapid (occurring in 15 to 30 seconds) and that the compensatory rise occurs so quickly (1 to 2 minutes) that it is never possible to be sure that one has found the low point and in many instances this must have been missed. With regard to subjective symptoms it was found that these varied greatly in their severity and that neither their severity nor the time of their occurrence had any relation to the presence or absence of the fall in systolic or diastolic pressure. Furthermore, the presence or absence of a marked blood pressure fall could not be shown to have any definite relation to retinal arteriosclerosis or evidence of renal damage, as the charts demonstrate. Charts 3, 4, 6, 7, 8 and 9.)

THE REACTION IN ANGINA PECTORIS

Before reporting the results of the reactions noted after the use of nitrites in attacks of so called "ambulatory" angina pectoris, it is perhaps worth noting that in every one of the eight patients studied the pressure during the attack and before treatment was instituted was found to be well above the usual pressures noted in these persons when they were free from attacks. This is contrary to the experience of Harlow Brooks

in these cases¹⁴ but in accord with the writer's previous experience.

(1) The action of nitroglycerine was studied in fifteen attacks occurring in eight patients following 1/200 to 1/50 gr. by mouth. No change or a slight rise in systolic pressure occurred within the first minute. Usually within three minutes a marked drop in systolic and a slight drop in diastolic pressure took place. The maximum drop in systolic and diastolic pressure usually occurred within ten

minutes (Charts 10, 11, 12, 14, 15 and 16)

Relief in Pain Partial relief of pain ordinarily was noted in from one to two minutes, and complete relief except for residual soreness at times occurred within a minute and a half, and if the dose had been sufficient to control the situation had usually been established before the end of five minutes. It was evident that considerable or occasionally complete relief of pain took place in some cases before

Chart 5. Nephritis with hypertension in a 16 year old girl. Note lack of response to nitroglycerine.

CHART 7 Arterial hypertension. Note marked response to amyl nitrite in spite of presence of tachycardia and other symptoms and in the presence of marked retinal arteriosclerosis

CHART 8 Arterial hypertension Note effect of animated conversation on blood pressure

any drop in diastolic pressure had been noted, and was well established before any effect more than a five mm drop had been observed even on the systolic pressure (See Charts 10, 11 and 12) In one instance complete relief had occurred when both systolic and diastolic pressures were within 5 mm of the point at which they were first observed (Chart 10) and in another (Chart 14) no drop whatever but an actual rise in diastolic pressure took place although there was at the time complete relief of the pain (The shaded areas on the charts which are intended to indicate the degree of pain are based on the patient's answers to repeated questioning during the tests)

(2) In the three attacks that were studied by the use of amyl nitrite the usual abrupt fall in 30 seconds followed by a quick rise in a minute and a half was found In two instances the pressure remained for the next twenty minutes at a distinctly lower figure than before the administration of the drug.

Relief of Pain. In no instance did the relief of pain correspond to the low pressure reading. One patient in whom, as is shown in Charts 11 and 13, the pressure had fallen abruptly, a drop of 70 mm systolic and 30 diastolic, stated that the pain had not changed in the slightest Three seconds later sudden relief took place, as he said, "like pricking a toy balloon" On a second patient (see Chart 12) thirty seconds after amyl nitrite when a drop of 70 mm systolic and 32 mm diastolic had occurred, there had been no change at all in the intensity of the pain but at the end of

one minute, although the diastolic pressure had returned to its former level of 110 mm and the systolic had risen to 180 mm, or three-quarters of the way back to the starting point, the pain had markedly diminished and after two and a half minutes had completely disappeared although the pressure readings were at that time very nearly what they were before the inhalation of the drug

Comment It is evident from the above that the relief from pain experienced after nitrite therapy in angina pectoris is independent of the decrease in systemic blood pressure—diastolic or systolic This certainly suggests that such relief is probably not due to nitrite dilation of the peripheral vessels The only other known action of nitrites which could relieve the pain, then, is the action on the coronary arteries—and if increased flow through the coronaries is the mechanism of the relief, the cause of the pain must be an ischemia of the heart muscle It is probable, then, that anything which causes an increase in the work of the heart such as excitement or exertion, with the known increase in peripheral blood pressure and heart rate which accompany them, causes in these patients a temporary ischemia of heart muscle The underlying cause of the whole picture must therefore be deficient coronary circulation which is incapable of supplying the physiologic needs of the musculature of the heart during periods of stress.

In connection with the reaction of patients with angina pectoris to nitrite therapy brief reference will be made to one patient, a lady of 76 years of

CHART II *Angina pectoris* Response of the same individual to amyl nitrite and nitroglycerine in two attacks occurring within an hour

FIGURE 12. Angina pectoris. Response to amyl nitrite and nitroglycerine. Note but no correspondence between pressure levels and pain relief.

CHART 13 Angina pectoris Chart of pressure curves and pain relief in cases illustrated in Charts 11 and 12 drawn to a different scale to show more clearly the lack of correlation between fall in pressure and pain relief

age, in whom the administration of nitroglycerine gr 1/100 per os because of anginal pain of moderate severity, was followed, after the usual relief had been experienced, by a recurrence of much more severe and viselike pain, sweating, pallor and a further marked fall in blood pressure (Chart 16). All our clinical observations including electrocardiographic studies before and after the attack, confirmed the impression that while under observation the patient had suffered an occlusion of a branch of a coronary artery. This case will be reported later in detail. One certainly is led to suspect that in this instance the action of the nitroglycerine may have been a factor in bringing on or hastening the thrombosis of the coronary artery involved.

SUMMARY

Studies of the rapidly acting nitrites, nitroglycerine and amyl nitrite, in the usual therapeutic doses, on normal people, persons suffering from arterial hypertension and from the anginal syndrome showed the following results:

1. The usual symptoms, tachycardia, flushing, headache, etc., varied greatly and appeared quite independent of pressure levels.

2. Normal human beings after the application of nitroglycerine by mouth or hypodermically showed no consistent change in diastolic pressure. The systolic pressure also underwent no consistent change although there was in some instances a slight tendency downward.

3. The reaction of normal human beings to amyl nitrite was a sharp fall

in thirty seconds followed by a quick rise to above the previous level in about two minutes. Later blood pressure readings approximated the initial figures.

4. Patients with arterial hypertension with and without severe renal damage showed similar reactions. After nitroglycerine there were no consistent changes in either systolic or diastolic pressures. After amyl nitrite they showed a sharp drop in systolic pressure similar to that seen in the normal in the first half minute followed by a compensatory rise at times exceeding the former level. The diastolic pressure in some instances underwent a similar but less marked variation and in others almost none. Although the presence of a marked diastolic drop may indicate an early stage of arteriolar disease, as suggested by Stieglitz, it did not bear any definite relation to the presence or absence of sclerosis of the retinal arterioles in the patients studied. The rapidity of the drop and the compensatory rise made an accurate determination of the extent of the drop impossible.

5. In the presence of the anginal syndrome nitroglycerine caused a marked drop in systolic pressure within two to five minutes at times preceded by a slight rise in the first minute. The diastolic pressure usually but not always showed a fall also. After amyl nitrite the usual sharp fall in systolic and diastolic pressure occurred followed quickly by the compensatory rise. In both instances pain relief occurred promptly but was quite independent of pressure levels.

CHART 14 Angina pectoris Response of three different individuals in attacks Note absence of fall in diastolic pressure in second case in spite of complete pain relief

Chart 15. Angina pectoris—woman 76 years old who had previously had coronary occlusion illustrated in Chart 16. Note decrease of response to tablets of nitroglycerine when had been kept in the house about 4 months (marked nitroglycerine 'old' on chart).

CHART 16 Angina pectoris followed by coronary occlusion. Note favorable response to nitroglycerine followed by return of severe viselike pain and a much more marked and permanent fall in blood pressure

CONCLUSIONS

1 Except for a very transient fall in blood pressure after amyl nitrite, neither it nor nitroglycerine, when used in the usual therapeutic doses, causes any consistent blood pressure changes in normal human beings or in persons with arterial hypertension with or without severe renal damage or retinal arteriolar sclerosis.

2 The fall occurring after the use of amyl nitrite is so rapid and transitory and so independent of subjective symptoms, that it is impossible to measure it accurately by taking blood pressure determinations in the ordinary way. This fact greatly decreases its usefulness as a test for arteriolar relaxability in estimating the prognosis in arterial hypertension.

3. In persons suffering from attacks of angina pectoris of the usual ambulatory type, a rapid fall in systolic and usually in diastolic pressure takes place after the use of these drugs.

4. The pain relief which occurs in these cases of ambulatory angina is independent of the pressure levels and therefore apparently independent of the action of the nitrites on the peripheral vessels but due to their action in increasing coronary circulation.

5. The cause of the pain in ambulatory angina is probably an ischemia of the myocardium dependent upon an insufficient blood supply due to disease of the coronary arteries.

Auricular Flutter and Complete Heart Block: With Restoration of Sinus Rhythm and A-V Conduction*

By LESLIE T. GAGER, M.D., *Clinical Professor of Medicine, George Washington University, Washington, D. C.*

NEITHER auricular flutter nor complete heart block are by themselves extraordinarily uncommon and it is safe to say that they would be even more familiar were the presumptive signs and symptoms of each borne in mind and the means taken for definitive diagnosis. The co-existence of these two disorders of the heart beat, however, is a clinical rarity. Previous to the example which is here reported, I find in the literature a total of fifteen cases of auricular flutter occurring in the presence of total auriculo-ventricular block, while in two patients only, those of Schott⁶ and of Gallemarts,¹¹ was there the joint restoration, under treatment, of sinus control and A-V conduction.

CASE REPORT

N. R., a negro laborer aged 70 years, worked until the day before his admission to the George Washington University Medical Service, Gallinger Municipal Hospital, on Jan. 20. His complaints were increasing shortness of breath and swelling of the ankles.

The family history was irrelevant and the patient had never been seriously ill. Vene-

real infection was denied and he had been moderate in the use of alcohol and tobacco.

His present illness began three weeks before admission with chills and fever and a dry cough, followed by dyspnea on effort, occasional palpitation and slight edema. He was able to sleep comfortably, his appetite and digestion were good, the bowels were regular and there was total absence of pain, fainting or convulsions.

The physical examination showed a well-developed, sparsely nourished old man lying flat in bed. Respirations were 16, regular and quiet. The jugular veins were not distended.

The pupils were active and the knee jerks present.

The retinal vessels were found without notable changes, the peripheral arteries were markedly sclerotic.

The apex of the heart gave its impulse in the sixth interspace 10 cm. to the left of the midsternal line. Apex and pulse rates were 44 per minute, the rhythm was regular. The blood pressure was 122/78. Clear heart sounds coincided with the apex rate, no intervening sounds were made out. The chest was full and the lungs were moderately emphysematous. There were numerous râles at the bases.

The liver edge was at the costal margin, not tender and the wall of the abdomen was relaxed.

Pitting of the ankles was present.

*Case presentation at clinic for the American College of Physicians, George Washington University Hospital, March 28, 1931.

The urine showed a specific gravity of 1.022, a faint trace of albumin and an occasional hyaline cast. Hemoglobin was 70 per cent, white blood cells 7,000, with poly-

morphonuclears 53, band forms 12, large mononuclears 5, and lymphocytes 30 per cent. There was a one plus Wassermann reaction of the blood.

A teleroentgenogram gave an aortic diameter of 7.4 cm, and the transverse cardiac diameter 16.1, with a thoracic width of 30.0 cm.

The electrocardiogram (figure 1) confirmed the clinical diagnosis of complete heart block, with a ventricular rate of 44

auricular or ventricular rate and was resumed from Feb 9 to Feb 16, at 60 minims (4 cc) per day, also without effect.

Quinidine sulphate was prescribed on Feb 16, in doses of 0.4 gm (gr vi) given three times daily.

On the first day of its administration, there occurred what the patient described as a "shaking spell all over" which lasted three hours and was without fever. Sub-

FIG. 1 Auricular flutter, rate 274, complete heart block, ventricular rate 44. Supraventricular type of QRS indicates origin in bundle. (Electrocardiograms by G. Edward Smith.)

beats per minute, and in addition it disclosed the presence of auricular flutter at 274 beats per minute.

The course of the patient was afebrile, the apex and pulse rates ranged from 42 to 52 per minute and respiration from 16 to 20.

Treatment at the outset in the presence of congestive heart failure, consisted in rest in bed. This was supplemented by full doses of digitalis, and in the 12 days from Jan 21 to Feb 2 the patient received 250 minims (62 cc) of standardized tincture without apparent effect either on the flutter or on the block. The flutter varied from 280 beats to 250 beats per minute. Between Feb 2 the digitalis was discontinued for a week without change in

sequently, the pulse and apex rates were found from 60 to 70 beats per minute, with a dominant regularity frequently broken by beats which were interpreted as premature. The electrocardiogram taken on Feb 24 (figure 2) shows the persistence of this arrhythmia and its nature. There has been a return to normal sinus rhythm, most clearly seen in Lead III. Lead II shows a period of auricular silence—sino-auricular block?—followed by ventricular escape.

As quinidine was continued the ventricular rhythm became entirely normal and on March 15 the drug was discontinued. On March 21, the electrocardiogram (figure 3) reveals normal sinus rhythm and its control of the ventricles. The same profound effect

FIG 2 The response to quinidine. Lead III best shows normal sinus rhythm and control of the ventricles. P-R interval is 0.24 sec. Lead II shows a transitory phase with auricular silence and ventricular escape. The change in amplitude of the QRS waves is distinct.

FIG 3 Complete restoration of sinus control, but persistence of delayed A-V conduction. No quinidine has been given for one week and no digitalis for five weeks. The QRS groups in II and III have decreased in amplitude and show notching.

the P-R interval to 0.24 sec which was noted on Feb 24 is still present (For over a month, no digitalis has been given) The QRS complex occupies 0.08 sec, but is somewhat slurred and split The T wave is upright in all leads The rate in this record is 82

On March 25, an occasional prolonged pause and then a beat suggested the return of ventricular escape Quinidine was resumed, and upon discharge March 28, the rate was 72 to 76, the rhythm regular

The mental as well as the physical improvement of the patient under treatment is of interest It was noted at the time of admission that the patient was cooperative but his mind was dull and blurred and his responses sluggish He became ambulant after the first week, except during the first few days of quinidine therapy, but there is a note on Feb 25 that there is marked improvement in the mental condition along with the restoration of the normal heart rate

In summary, a man with arteriosclerotic heart disease, without cardiac hypertrophy or evidence of pre-existing hypertension, and without the history of Adams-Stokes attacks, suffering from congestive heart failure, showed complete heart block and by electrocardiographic demonstration, auricular flutter The auricular rate ranged from 260 to 280, the ventricular from 42 to 50, in the electrocardiograms Full doses of digitalis were ineffective but quinidine had a prompt action in abolishing flutter and restoring normal sinus control and heart rate A prolongation of A-V conduction time persists and there is further evidence of myocardial disease in the distortion of the QRS complex

REVIEW OF LITERATURE

It is noteworthy that clinical knowledge of auricular flutter begins with a patient whose complete heart block

furnished the incentive for further graphic study and then facilitated the analysis of the rapidly and regularly occurring "a" waves in the polygram

This patient of Ritchie's¹ was a man of 55. He came under observation with a pulse rate of 36 and a history of shortness of breath and attacks of faintness and giddiness since pneumonia six months before The blood Wassermann reaction also was positive After a period of normal auricular action, in June 1905, flutter at 274 beats per minute was discovered Observations were continued over a period of nine years^{2,3} At first paroxysmal or intermittent, the flutter became persistent in 1908 The ventricular rate ranged from 32 to 36, was occasionally elevated by premature beats and during one period showed groups of rapid beats (11 per minute) For two periods only, in 1913, did the auricular rate drop to normal, once after strophanthin and digitalis The Adams-Stokes attacks ceased after the establishment of flutter

In a woman aged 39 years, with rheumatic heart disease, Hertz and Goodhart,⁴ in 1909, found auricular flutter persisting for ten months at a rate from 216 to 230, with a ventricular rate as low as 44, though usually higher, from 72 to 120

A third patient was reported by Donzelot and Pezzi⁵ in 1914, a woman of 62 years, whose auricular and ventricular rates respectively were 300 and 35 to 40

Schott,⁶ in 1920, discussing ventricular standstill and the Adams-Stokes syndrome recorded these phenomena

in a woman aged 60 years who had had acute rheumatic infection six years before, and now showed runs of auricular flutter at 270 to 280 beats per minute and a ventricular rate sometimes in 4:1 ratio, during the course of which ventricular standstill was observed to occur, and sometimes independent ventricular rhythm at 58 beats per minute. Under digitalis the flutter merged into fibrillation and this into sinus rhythm, with recovery of excellent functional capacity. Repeatedly her life was saved, during the syncope of ventricular stoppage, by fist-blows over the heart.

Vinnis,⁷ in 1921, reported a man of 68, with hypertension of 285/125 and no symptoms except vertigo, with respective rates of 240 and 35 for auricle and ventricle.

Syphilis and the precocious arterial degeneration due to it were held responsible by Arillaga and Waldorp⁸ for the aortic insufficiency and complete heart block in a man of 42 years. The ventricular rate was 25 to 29, the auricular tachysystole 225 to 260. No improvement resulted from active anti-syphilitic treatment.

In 1922, Keating and Hajek⁹ witnessed the onset of flutter during her hospital stay in a woman aged 50 years who for four years had suffered from attacks of collapse and momentary unconsciousness. On admission, examination and electrocardiogram showed a simple tachycardia, rate 140. A week later, there occurred auricular flutter, rate 360 and complete block with ventricular rate 30. The auricular beats were audible. Later records showed a normal auricular rate, still later im-

pure flutter and fibrillation with many premature ventricular beats.

Wiltshire,¹⁰ in 1923, made particularly interesting observations in the case of a man of 63 years suffering from complete heart block, and periods of ventricular standstill lasting up to 67 seconds and occasioning severe Adams-Stokes attacks. During some of these periods of ventricular silence, auricular flutter was present, in others, sinus rhythm, in still others the auricles also were completely silent—in one record for 13 seconds during the attack and for four seconds after. It was observed that the auricular rate during one episode of ventricular standstill fell from 240 to 165, this slowing was considered evidence of exhaustion of the auricular muscle, presumably from lack of blood supply, for after the ventricles again began beating, the auricular rate rose at once to 214.

The patient of Gallemaerts¹¹ was a man of 62 years. There were attacks of asystole, the electrocardiogram disclosed ventricular bradycardia, complete A-V dissociation and auricular flutter. The use of quinidine caused reversion of the flutter to sinus rhythm, and made manifest a delay in conduction both in the main bundle and one of its branches. The syncopal attacks ceased.

Hall¹² found a history of bradycardia and fainting in a man of 62 years who sought treatment for intermittent claudication. The auricular rate was 270, ventricular rate 42. Right bundle branch block was present.

Willius,¹³ in 1927, described auricular flutter in a man of 50 with arteriosclerotic heart disease and congestive

failure Complete block had been established for five years The rates for auricle and ventricle were 236 and 36 Digitalis was not used in this patient, and quinidine had no effect This was the only example of the occurrence of auricular flutter with complete block in 108 cases of flutter discovered in the routine electrocardiography of 40,000 patients

Auricular flutter supervening in a woman of 50 years whose complete block had been observed for 11 years and whose history of slow pulse went back 20 years before this, was reported by Strauss¹⁴ The inciting cause of the flutter appeared to be a toxic adenoma of the thyroid Two months after thyroidectomy the rapid jugular pulse disappeared and the electrocardiogram confirmed the return of sinus rhythm The block persisted.

In the course of their large experience with flutter, Parkinson and Bedford¹⁵ encountered a man aged 74 years with congestive failure and slow pulse of two years duration The auricular rate was 270, the ventricular, 35 Under digitalis, the flutter was converted to fibrillation and two days later sinus rhythm was restored The complete block remained During flutter the auricular sounds were clearly audible at the apex, under sinus rhythm the auricular sounds were again heard but not so loud as with flutter

Henderson and Rennie¹⁶ reported auricular flutter with full heart block in a man aged 73 years who complained of weakness, fatigue and epigastric fullness The auricular rate was 201 and that of the ventricles 28 to 31 Atropine brought a slight in-

crease in ventricular rate but both conditions persisted and the patient died three months later

Finally, in 1930, Lian and Viau¹⁷ recorded their observations in a man of 54 years who came under treatment in 1927 for a complete block, with attacks of ventricular standstill and syncope, which disappeared under antisyphilitic measures In January, 1929, there were found complete heart block and right bundle branch block, auricular rate 84, ventricular rate 25 In April, 1929, the electrocardiogram showed flutter, at a rate of 242, ventricular rate 32 and left bundle branch block In May 29, following 25 mg of digitalin given over six days, the flutter disappeared, the complete dissociation remained, and the right bundle branch block reappeared

CRITERIA FOR DIAGNOSIS

When auricular flutter occurs singly, its presence is suggested by a regular persistent pulse of 120 to 170 beats per minute The diagnosis becomes reasonably certain if the pulse suddenly doubles in rate In other words, a 2:1 or 3:1 A-V ratio is suddenly converted to 1:1 rhythm But when transitions from one to another ratio are occurring frequently the pulse may not be regular, in the presence of the slower auricular flutter rates or of the higher auriculo-ventricular ratios, the rate of the ventricles may not excite attention For these and other reasons—such as the inconstant effect of vagus (carotid sinus?) pressure or of digitalization—recourse must be had to the electrocardiogram

As far as complete heart block alone is concerned, the idioventricular

rate is usually below 50 beats per minute and clinical diagnosis becomes the more assured as the rate falls to 40 and below. But total dissociation between auricle and ventricle is by no means stable; the ventricular rate, as in an aged physician under recent observation, may rise from 39 to 76 beats per minute, or the regular rhythm may be interrupted by ectopic ventricular beats or psychic influences and even changes in posture¹⁸ may produce the most striking changes in impulse conduction. In block, therefore, as in flutter, the evidence of the electrocardiogram is indispensable.

When, now, the two disorders of the heart beat are superimposed, the peripheral signs, such as apex and pulse rates, and the evidence of circulatory embarrassment, either transient in the form of Adams-Stokes attacks or in the more persistent congestive failure, are dominated by the block and ventricular insufficiency. Evidence of flutter must be sought in the way of abnormal auricular pulsations in the jugular veins or abnormal auricular sounds on auscultation either over the heart or over the jugular bulb. Fluoroscopy may disclose the auricular rate. But since these phenomena commonly are difficult, if not impossible, to elicit, once more the graphic methods must be looked to for an assured diagnosis.

PHYSIOLOGICAL CONSIDERATIONS

Without entering upon any extended discussion of the functions of heart muscle, particularly the properties of irritability, conductivity and rhythmicity which are especially concerned in the physiology of flutter and complete

block, it is possible to divide these cases into two groups.

In the first group are those in which the A-V dissociation was established prior to the onset of auricular flutter. Here perhaps the two disorders may be regarded as coincident in the course of progressive myocardial structural change; a definite interrelationship is lacking.

On the other hand, if flutter precedes, the possible effects of the rapid auricular impulses upon the capacity of the bundle for conduction or of the ventricle for excitation are to be considered. In experimental heart block Erlanger showed how increased auricular rate brought increase in the degree of dissociation; recently Herrmann and Ashman¹⁹ have discussed the mechanisms that may underlie both the gradual and the acute onset of complete block as well as of bundle branch block.

Certainly in the case which is here reported, as in the patients of Gallemaerts and Schott, the restoration of normal sinus rhythm would seem to have removed the factor of fatigue of the main bundle and thereby to have influenced the return of A-V conduction. In Lian and Viau's case the influence of flutter on bundle branch block is of interest. Parkinson and Bedford ascribe the 2:1 and 4:1 ratios (persistent 3:1 ratios are exceptional) to defective conductivity in the presence of flutter, the functional nature of which is shown by normal conduction when sinus rhythm returns.

The bearing which these facts have on treatment is that they suggest the importance of attempting, either by

digitalis or by quinidine or both, to restore sinus rhythm with the possibility of influencing A-V conduction

SUMMARY

A patient with auricular flutter co-existent with complete heart block was restored to sinus rhythm and A-V conduction by the use of quinidine sulphate. Physical and mental improvement resulted

Fifteen cases have been found in the literature showing the association of auricular flutter and total block and the clinical phenomena and criteria for diagnosis are reviewed

From experimental and clinical observations in partial block and from the results in three cases of complete block, the value of restoring sinus control in cases of auricular flutter is shown.

Primary Aplastic Anemia; A Discussion and Report of Two Cases*†

By JAMES B. CAREY, M.D., F.A.C.P., and JOSEPH H. TAYLOR, M.D.,
Minneapolis, Minn.

THERE are various toxic and chemical agents, which may so affect the bone marrow that it is incapable of forming blood elements, and a condition of profound anemia may therefore occur. Infectious diseases, which progress to severe stages of toxicity or septicemia; benzol, trinitrotoluene; arsenic, roentgen rays and radium emanations can all affect the hematopoietic system in such a manner as to produce the clinical picture of an aplastic anemia. In certain chronic blood disorders and malignancy, there often occurs an exhaustive aplasia of the blood-forming tissues.

Excluding all known etiologic factors, however, there remains the primary or idiopathic case. Ehrlich¹ first described such a clinical entity in 1888. Since his report other terminology has been suggested. Pappenheim² suggests "a-regenerative anemia" and later Schneider³ suggests "toxic paralytic anemia" or "toxic anhemopoietic anemia". However, since at autopsy these cases show a completely aplastic condition of the bone marrow, a hypo-

plasia so profound that not even the normal amount of blood elements is found, with little hint as to the possible cause, it would seem that Ehrlich's original term is the most applicable. Any other designation implies etiologic factors, and none has been known.

Aplastic anemia patients are usually young adults or individuals of early middle age, in fair state of nutrition, showing pallor of either grayish or yellowish tinge, with hemorrhages into skin and mucous membranes. There is usually stomatitis and glossitis, progressing often to an extreme phlegmonous induration or gangrenous slough, and a septic type of temperature which may be due to the mouth lesions, especially as they usually become secondarily infected.

Further study of the case should reveal these other positive data.

1 Extreme anemia (counts as low as 500,000 or less with hemoglobin often too low to read accurately). The anemia is of the hypochrome type with no evidence of blood regeneration.

2 Leukopenia which also may be very low (1,000) with a relative lymphocytosis.

3 Thrombocytopenia, platelets may be too few to count accurately, usually less than 75,000.

*From the Department of Medicine, The Nicollet Clinic. Read before the Minnesota Society of Internal Medicine, April 13, 1931.

†Received for publication, April 14, 1931.

Pathologically, there is found an extreme hypoplasia, or aplasia of the bone marrow. The marrow grossly is soft, yellow and almost completely replaced by fat. The microscope confirms this gross appearance of inactivity by revealing extreme hypoplasia or complete aplasia of cellular structures.

The outcome of all cases is fatal and no treatment up to the present time employed has been of the slightest avail.

Hirschfield³¹ gives a complete bibliography up to 1911.

Sheard,⁴ in his monograph on pernicious anemia and aplastic anemia, has covered the bibliography up to 1923 and discovered about 125 authentic cases. Since 1921 there have appeared in the literature reports,⁵⁻²⁴ presenting about twenty further adult cases. Schneider³ mentioned sixty cases found up to 1918. There are several discussions of primary aplastic anemia based upon an indeterminate number of cases²⁵⁻³³. Many of these cases and discussions are in inaccessible literature; those papers found dealing with various phases of the subject are sometimes indefinite as to the actual number of cases on which the discussions are based. It may be estimated with reasonable accuracy, however, that not over 150 cases of primary aplastic anemia so far have been reported. A few cases reported among children were rather obviously anemias of hemorrhagic and aplastic type, following directly as the result of severe infections, and must therefore be excluded when considering only idiopathic cases. Some of Sheard's mentioned reports are of this category. There are

many cases of pernicious anemia reported with so-called aplastic tendencies, meaning that there may be a stage in pernicious anemia when the bone marrow becomes aplastic, all blood elements consequently becoming reduced, hemorrhages occur and the patient dies.

The diagnosis of primary aplastic anemia is, in fact, often difficult and lies somewhere among several conditions; hemorrhagic and aplastic type of blood reactions occurring secondarily to sepsis, infection, sudden grave hemorrhage, pregnancy, poisons (benzol, trinitrotoluene, arsenic) and exposure to x-ray and radium. No difficulty is encountered if the primary agent can be determined. There are four diseases, however, which may cause confusion; thrombocytopenic purpura, pernicious anemia, aleukemic leukemia and agranulocytic angina. In leukemia, even in the aleukemic stage, there will probably be adenopathy and splenic enlargement and certain characteristic elements in the blood picture. The anemia will probably not be so profound, nor will the hemorrhagic features be so abundant or severe.

In pernicious anemia the history is usually of much longer duration and contains references to gastrointestinal symptoms, paresthesia and glossitis. There are evidences of hemolysis in skin, urine, duodenal contents, blood serum and feces. The anemia in pernicious anemia is not so profound until the end stages at least, nor are the hemorrhagic features prominent, although often present. In pernicious anemia there is also usually present an achlorhydria and usually evidence of subacute combined degener-

eration (posterolateral sclerosis) of the spinal cord. The platelet count is not likely to be so completely reduced, nor is there such a marked leukopenia. The anemia is of the hyperchrome type.

In thrombocytopenic purpura the hemorrhagic features are more marked, and the anemia and leukopenia less so than in aplastic anemia. The morphology of the blood elements is practically normal.

Agranulocytic angina is a condition in which a severe gangrenous stomatitis develops and is accompanied by a blood picture of complete or almost complete absence of granular (polymorphonuclear) leukocytes. The red blood cells and hemoglobin may remain within normal range. The patients are usually middle aged females, and the disease is rapidly fatal (within two weeks ordinarily). There is, on account of the relatively normal hemoglobin and red count, no pallor, and the hemorrhagic features are usually absent. Piney has mentioned the agranulocyte reaction as sometimes occurring in aplastic anemia, but none of the formally reported cases have shown such phenomena.

Pathologically, the differentiation is not difficult from an examination of the bone marrow alone⁸⁴. In aplastic anemia a soft, yellow, fatty hypoplastic or aplastic marrow is evident, in pernicious anemia the red marrow is increased, and shows hyperplasia. In thrombocytopenic purpura there is also a red, cellular marrow with an increase of blood elements and decrease of fat. The degree and kind of hyperplasia is not, however, that of pernicious anemia. In leukemia there is

found a preponderance of lymphatic elements in the marrow. Further post mortem studies show in pernicious anemia the cord sclerosis or in leukemia the various characteristic glandular and splenic overgrowths. The bone marrow in agranulocytic angina does not show any characteristic changes of red cell elements, but granular cells are absent.

Two cases of idiopathic aplastic anemia are herewith described, and commented upon.

Mr S S, a farmer aged 33 years, a resident of Minnesota, consulted one of us (J B C) on November 5, 1929, complaining of weakness and swelling of the abdomen. He said that in September, 1929, he first began to become easily fatigued while at his work. About this time he sustained a fall, bruising his left side, after which he noticed some abdominal swelling. His local physician told him he probably had some fluid in his abdomen. He became weaker from that time until consulting us, but did not lose weight. He had no gastro-intestinal symptoms other than a capricious and variable appetite and the feeling of distention. He had daily bowel movements, which retained a normal color and consistency. There were no urinary symptoms. His skin became pale and slightly yellow, but there was no itching. His tongue had occasionally been sore.

The only illness he had had in the past was an attack of pleurisy in 1924. His family history was negative.

Physical examination on November 5th showed a pale man, rather dyspneic on slight exertion, with abdominal distention. He was fairly well nourished, but of poor muscular tone. The skin and mucous membranes were very pale, and slightly yellow, but not jaundiced. The hair had begun to turn gray. The tongue was moderately atrophic, with a whitish area on the right side, the site of recent glossitis. The heart was normal, except for a systolic "hemic" murmur heard at the base. The lungs were clear. The abdomen was tympanitic, mod-

erately distended, but revealed no masses or other abnormalities. The liver was barely palpable at the right costal margin and seemed of normal consistency. The spleen was palpated with difficulty on account of the distention and was slightly tender. The reflexes were present and normal, and vibration sense over the inner malleoli as estimated by the "C" tuning fork was normal. There was slight edema of both ankles, extending one-third of the distance up the tibiae.

Gastric secretory analysis showed a complete absence of free hydrochloric acid with a total acidity of 27. Fluoroscopic examination of the stomach, after ingestion of a barium meal, showed a large atonic organ without defects. The barium filled bowel, by fluoroscope, was likewise atonic and contained much gas, but was otherwise negative. The urine was light amber in color, 1017 specific gravity and acid in reaction, with 2+ albumen, but no sugar. A few blood cells and an occasional hyaline cast were seen. There was a trace of urobilinogen and no urobilin. The blood serum bile index was 8 to 9. Blood Wassermann and Kahn reactions were negative. Blood pressure was 110/80. There was no lymphatic glandular enlargement. An examination of the blood showed coagulation time 4'15", bleeding time 12', and 50,000 platelet count. Hemoglobin was less than 10 per cent and the red blood cells numbered 500,000. There were 1,250 white blood cells with 64 per cent of polymorphonuclears, 23.5 per cent lymphocytes, 12 per cent monocytes and 0.5 per cent eosinophils. The polymorphonuclear elements showed a distinct shift to the left, with several young and immature forms. There were none of the so-called pernicious anemia neutrophils present. The smears of the red blood cells showed a distinctly aplastic tendency, with more anisocytosis and poikilocytosis than normal and only an occasional hyperchromatic or polychromatic cell; there was, however, no achromia. There was also an occasional nucleated red cell seen.

The patient was placed in the hospital and grouped for transfusion. He was found to be a Group IV with, however, rather atypical agglutination reactions to Group IV sera. A transfusion of 375 cc of citrated blood was given on November 6th. There was a moderate reaction about two hours following the transfusion, controlled by 10 m adrenalin given by hypodermic injection subcutaneously. Liver extract (Lilly 343), 6 vials daily in orange juice, was begun and the patient placed upon the "Minot-Murphy" liver-containing diet.

The patient was given two other transfusions on the 9th and 17th, each followed by a very severe reaction, and neither of these additions of blood had appreciable effect upon the blood count, as even from the records below. A glossitis developed which became very severe, and spread onto the under surface of the tongue and to the buccal membrane. This lesion was undoubtedly responsible for the slight elevation of temperature noted constantly (100° to 101°, and at the time of transfusion reaction, 104° to 106°). Bleeding from the gums and rectum subsequently occurred; 50 cc of whole blood was used intramuscularly on two occasions, November 15th and 18th, in an unsuccessful attempt to control these hemorrhages. Petechial and purpuric spots appeared in scattered places over the body, and finally a day before death the surface of the abdomen was almost solidly covered with subcutaneous hemorrhages. The appetite remained good until the last two days, and the six vials of liver extract were continued until the last day. Death occurred November 27th, after a period of unconsciousness with elevated pulse (120), temperature (104°) and Cheyne-Stokes' respiration. An autopsy request was refused.

A few of the blood counts are herewith given (those showing transient effect of transfusion and whole blood injections are eliminated).

Nov. 7	Hgb	20%	Rbc	950,000	
Nov. 11	Hgb	10%	Rbc	800,000	
Nov. 16	Hgb	12%	Rbc	580,000	— no reticulocytes
Nov. 23	Hgb	15%	Rbc	520,000	
Nov. 27	Hgb	10%	Rbc	450,000	Wbc 8,600, no reticulocytes.
					(This count was done just before death.)

COMMENT

The phlegmonous, almost gangrenous lesion of the tongue had been described in many of the other cases of aplastic anemia reported in the literature. The temperature also is a common finding in this type of anemia. Although the blood bile index was slightly elevated, there were no other very striking evidences of extreme blood destruction, such as are often seen in end stages or crises of true pernicious anemia. The bile pigments of the urine were normal, the stool was of normal color and neither skin nor sclera were at any time marked by jaundice.

The blood count was very low, and did not react to the stimulation of liver, liver extract, blood transfusions or whole blood injections. There was free bleeding from the gastro-intestinal tract and subcutaneous hemorrhage. There was an achlorhydria present, but no signs of combined cord sclerosis. There was an absolute leukopenia at the beginning. The terminal rise seen may have been the result of the transfusions and whole blood, or both. The history of the illness was of short duration and showed a rapid progression to the fatal termination.

The second case is that of a white male age 42 years. He presented himself to one of us (JHT) for examination on October 15, 1930, complaining of weakness, dyspnea and "anemia." About a month previous to this admission he had had a severe sore throat with fever, for which he remained in bed for two weeks. During this time he had palpitation, became weak, suffered dull headache and experienced occasional slight bleeding from the gums. These symptoms all continued and were still complained of when he consulted us. His family history was nega-

tive as to any anemia or other constitutional diseases. In the fall of 1929 he had had some epigastric distress and heartburn, for which he consulted a physician, who made a diagnosis of duodenal ulcer, and placed him upon diet and medical management. He obtained relief gradually from these symptoms, and had regained what he considered to be normal health at the time when he suffered the severe angina mentioned.

The original physical examination showed a fairly well nourished man of rather poor muscular tone. There was marked pallor of the skin and mucous membranes, but no jaundice. The pupils reacted to light and accommodation normally. The sclera were clear. There was moderate gingivitis at this time, but no stomatitis or glossitis. The tongue was not atrophic. The breath was foul, and there was hypertrophy of the tonsils with evidence of recent hemorrhage from the right one. The heart and lungs were normal. Neither the liver nor spleen were palpable. There were no masses, fluid or other abnormalities revealed by abdominal palpation. Deep reflexes and vibration sense were normal. Examination of the gastro-intestinal tract after ingestion of barium by fluoroscope was entirely negative. Urine examination revealed a specific gravity of 1.013, acid reaction, no albumin or sugar, no bile or bile pigments. There were no casts, but an occasional red blood cell was recorded. Numerous stool examinations, made during his subsequent hospital sojourn, were negative for occult blood, parasites and ova. Blood Wassermann and Kahn reactions were negative. Gastric secretory analysis showed free hydrochloric acid 49, total acidity 69, blood bile index was 4 to 5. Examination of the blood resulted in the finding of a hemoglobin of 35 per cent (Dare), red blood cells 1,960,000, color index 0.92, white blood cells 2,100, polymorphonuclears 20 per cent, lymphocytes 75.5 per cent, monocytes 4.5 per cent. Bleeding time was 13 minutes and coagulation time 4 minutes, 45 seconds. The blood smears were essentially normal and remained so. The patient was hospitalized. The general hospital diet was ordered, and one ampule of Ventriculin was administered three times daily. The use of the Ventriculin was continued until the pa-

tient became too weak to eat or drink anything during the last two days of his life. During his stay in bed he gradually developed a stomatitis, which, as in the previous case, became very severe. Smears showed Vincent's organism and much secondary infection.

The patient was grouped and transfused twice, on Oct 27 and Nov 5. Following both transfusions, there were very severe reactions with chill and elevation of temperature. Just as in the previous case, these transfusions had no appreciable effect upon the blood counts, as seen by the following record: Oct 22, hemoglobin 46 per cent (Sahli), red blood cells 2,000,000, white blood cells 8,000, no reticulocytes. Oct 31, hemoglobin 47 per cent (Sahli), red blood cells 2,300,000, white blood cells 6,000. Nov 4, hemoglobin 42 per cent (Sahli), red blood cells 1,650,000, white blood cells 6,000, no reticulocytes. The increase in the leucocytes was undoubtedly due to the mouth infection, and perhaps also influenced by the transfusion and continuing hemorrhages.

Fibrogen was given in one and two cc doses subcutaneously on numerous occasions in the last few days in an attempt to stop the hemorrhages, and on Nov 6th 20 cc of whole blood was injected intramuscularly—all without effect on the bleeding.

During the seventeen days in the hospital, the temperature ranged from 98° to 104.8° F, the pulse from 76 to 116 and the respiration from 20 to 34. He suffered repeated, almost continuous, hemorrhages from the gums; was very uncomfortable on account of the stomatitis and finally after several large gastric hemorrhages, he died on Nov 7, 1930.

An autopsy was performed on the same day by Dr. N. M. Levine of the Department of Pathology of the Medical School of the University of Minnesota from whose complete and detailed report the following positive and pertinent findings are taken. There were diffuse ecchymoses over the trunk, and also scattered petechiae over

neck, chest and upper abdomen. There were also small petechial hemorrhages internally on the surface of the heart, pleural and peritoneal surfaces. The heart was otherwise normal and likewise the lungs, except for hypostatic congestion and edema of the latter. The liver was of a pale brownish red color. On opening the stomach, no ulcer was found, but submucous hemorrhages were numerous. The kidneys were normal, except for petechiae in the pelvis. The spleen weighed 175 gm, and was normal grossly and in cut section. The bone marrow of the upper part of the femur was uniformly yellow and fatty, that of the ribs was yellowish pink. The anatomic diagnosis was primary aplastic anemia with multiple hemorrhages. The bone marrow, in microscopic section, showed marked hypoplasia of all elements and likewise a marked decrease of leucocytes was especially noted.

COMMENT

This case proved to be a primary aplastic anemia by autopsy findings and showed essentially the same picture and clinical course as the first one detailed. In this second case, the onset was precipitated by an infection—a severe sore throat. The course was practically the same in both cases, progressive weakness, multiple and repeated skin and visceral hemorrhages, the development of severe stomatitis, gangrenous in the first and complicated by Vincent's infection in the second. There was no stimulation of blood regeneration in either case by use of liver, liver extract or hog stomach extract. Injection of whole blood had no effect on the tendency to hemorrhage or the thrombocytopenia in either case.

The Use of Sulphur for the Production of Fever in Peripheral Vascular Diseases*†

By LORENZ M. WALLER, M.D., and EDGAR V. ALLEN, M.D., F.A.C.P.,
Fellow in Medicine, The Mayo Foundation, Rochester, Minnesota

THE artificial induction of fever as a therapeutic measure in peripheral vascular disease has been well demonstrated. Its value rests on an increase in the circulation through the extremities, as demonstrated by determinations of cutaneous temperature. Brown and his co-workers have shown that the temperature of the skin increases to a far greater degree than the temperature of the mouth when fever is artificially induced, and have expressed the belief that this excessive increase in temperature is due to vasodilation. A vaccine consisting of *Eberthella typhi* (*Bacillus typhosus*), *Salmonella paratyphi* (*Bacillus paratyphosus A*), and *Salmonella schottmulleri* (*Bacillus paratyphosus B*), injected intravenously, serves admirably for the production of fever. Pain is also alleviated. There are four disadvantages in the use of this vaccine. (1) the occurrence of a chill, (2) the absence of the desirable part of the reaction after repeated injections, (3) certain untoward effects, and (4) the comparatively short duration of the fever. The effect of the typhoid "h" antigen (Eli Lilly and Com-

pany) was studied by Barker, who found that, following 314 injections given to sixty-three patients, chill occurred in only 27 per cent. Malaise was less marked. The use of this antigen marked a distinct advance in protein therapy, for chill is assumed to be conducive to vascular thrombosis,¹ and is not useful in the treatment of peripheral vascular disease. The untoward complications following intravenous injections of typhoid and paratyphoid vaccine have been emphasized by Hench². In a study of 10,000 injections in 2,500 cases he found unusual clinical phenomena subsequent to twenty injections in fourteen cases. Death occurred in three cases, a mortality of 0.12 per cent.

The history of the use of sulphur by injection has been reviewed recently by Mackay³. Subcutaneous injections were used by various investigators in 1907^{2,4,5}; these authors believed it lowered the temperature in bronchopneumonia and pulmonary tuberculosis. Intramuscular injections of sulphur in oil were first used by Schroeder⁶ in 1927 in the treatment of paresis. The literature regarding its use as a pyrogenic agent in syphilis, in other conditions of the nervous system and in

*Received for Publication April 3, 1931.

†From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

rheumatic disease has since increased considerably^{4,6 9-12,15-18}

Our attention was directed by Mackay⁸ to the use of sulphur in producing artificial fever. The first injection was followed by such satisfactory results (the healing of chronic ulcers of the toe in a case of thromboangitis obliterans) that further investigation was carried out. We hoped it would have the following advantages (1) safety of use for persons of advanced age, (2) production of prolonged fever, and (3) absence of disagreeable sequelae following injection. The first two desiderata have been realized. Schroeder¹⁴ wrote that intramuscular injections of sulphur are without danger to infants, or to senile persons. Our series is small, but complications have not been noted in persons ranging in age from thirty-five to sixty-five years. Fever is present for a prolonged period as compared with that following injection of typhoid vaccine. In our experience, pain at the site of injection constitutes the single contraindication to the use of sulphur by the intramuscular route.

TECHNIC AND DOSAGE

A 2 per cent suspension of sulphur in olive oil* is injected deeply into the lateral aspect of the middle portion of the thigh. Warming and shaking of the suspension distributes the sulphur more evenly in the olive oil. Injections can be given every four or five days, using alternate thighs, and increasing the amount at each injection. The amount of the first injection is 1 c.c. Schroeder¹⁴ increased each

succeeding dose by 1 c.c. of 1 per cent suspension of sulphur in oil, giving as much as 10 c.c. at a single injection, and a course usually of ten injections. The greatest single dose we have used was 35 c.c. of a mixture of sulphur, 2 per cent, and olive oil. In our experience amounts in excess of 2 c.c. of the 2 per cent suspension have little, if any, advantage over the smaller amount and cause greater pain and more marked chill. Repeated injections of amounts of 2 c.c. have always been followed by satisfactory febrile response. Apparently, in paresis, results of treatment are dependent somewhat on the height of the temperature achieved. In persons with peripheral vascular disease, increases in the temperature of the skin are usually as great when the general body temperature is 15° to 2°C above normal as with greater increases. We have never given more than six injections in sixty days to one patient. Typhoid vaccine was given intravenously between injections of sulphur.

MATERIAL STUDIED AND EFFECTS OF SULPHUR INJECTED INTRAMUSCULARLY

The present study deals with fifteen patients who received thirty-two injections of sulphur. The group includes ten patients with thromboangitis obliterans, three with arteriosclerotic occlusive disease of the extremities, one with painful paresthesia, and one with sclerodactylia. In five additional cases, in which patients received twelve injections, detailed observations were not made. The ages of the patients varied from thirty to sixty-five years.

*Supplied by the Abbott Laboratories, Chicago

Fever began on an average of seven and six-tenths hours after injection. The greatest afebrile period following injection was thirteen and five-tenths hours; the shortest, seven hours (tabulation). Small doses of the suspension of sulphur tended to produce gradual increase in the temperature of the body; following larger amounts, the increase in temperature was more rapid. The average maximal temperature, following all injections, was 102.4°F. It is interesting that relationship is lacking between the amount injected and the maximal temperature attained. Five injections of 1 cc each produced an average maximal tem-

perature of 102.1°F, and the temperature, after fourteen injections of 2 cc each, was only 0.3°F greater, an increase of no appreciable value. The average duration of the fever following all injections was fifty hours (figure 1). Dosage had direct influence on the duration of the fever, which averaged only twenty-seven hours following injections of 1 cc and fifty-four hours following injections of 2 cc. Larger amounts of sulphur produced fever of even shorter duration. Increase in the cutaneous temperature of the extremities occurred in a manner similar to that ob-

Fig. 1. Variations in the response of temperature and pulse rate to intramuscular injections of sulphur. The units laid off on the abscissa represent time in days.

served following intravenous injection of typhoid vaccine (figure 2)

Pain at the site of injection is the most disagreeable feature and the greatest objection to intramuscular injection of sulphur. Some patients complain little and others bitterly, but few wish the injection repeated, although none refused. In this regard, sulphur is far inferior to vaccine injected intravenously, for patients are unanimous in their preference to the discomfort caused by the vaccine as compared to that produced by sulphur.

The distress may be divided into continuous pain, and that which occurs only with movement of the extremity. The pain begins from one to three hours after the injection, and continues on an average of twenty-six hours before there is spontaneous relief. During an additional average period of fifty-one hours pain is present on moving the extremity, but absent when the leg is at rest (tabulation). This period occasions little complaint. The larger amounts of sulphur produced longer periods of pain.

30	4	76	490	102.6	15	35	112
35	1	125	525	103.0	10	16	66

Our attempts to prevent the pain by injecting other materials with the sulphur and oil, although not extensive, were unsuccessful. A local anesthetic was tried on three occasions without benefit. As was expected, its effects had largely worn off before the pain had begun. The addition of 5 c.c. of the patient's blood to the injected sulphur and olive oil was likewise without beneficial effect. Prevention of the pain is highly desirable, and further attempts should be made. Mackay⁸ has advanced experimental data as evidence that sulphur produced its pyrogenetic effect through local destruction of muscle, and it is possible that substances which may be found to prevent the pain will also eliminate the sharp, fever-producing effects of the sulphur. More intensive study of this phase of the subject is essential.

Thirteen of the fifteen patients had indolent ulcers associated with mild to very severe regional pain. In all cases, some degree of relief of pain was noted. After all injections of the suspension of sulphur in excess of 1 c.c., pain was only about half as severe as before. In one instance pain in the region of an ulcer disappeared entirely, but in general sulphur lacked some of the pain-relieving properties of vaccine injected intravenously. This study demonstrates that the fever and not the vaccine alone is responsible for the relief of pain with the patient at rest, in peripheral vascular disease. One patient with painful paresthesia of the feet did not receive relief from intramuscular injections of sulphur; later the pain was shown to be of central origin, for spinal anesthesia, with

complete motor and sensory paralysis, likewise failed to give relief.

Chill occurred following seventeen of the thirty-two injections of suspension of sulphur. In ten of these instances the chill was graded 1 in severity; in four it was graded 2; in two it was graded 3, and in one it was grade 4. Twenty-six injections of suspensions in amounts of 2 c.c. or less were followed by chill in thirteen instances (50 per cent), but the chill was of minor degree (graded 1 or 2) in all but one instance. Patients generally complained but little of the chill and it was not a contraindication to the use of sulphur.

An increase in the number of leukocytes followed the injection of sulphur in all the cases studied. Frequently they numbered as many as 45,000 for each cubic millimeter of blood. Study of the blood smears revealed definite increase in the percentage of neutrophilic leukocytes. The number and percentage of the leukocytes in the blood reached normal values on an average of ninety-eight hours following injection of sulphur.

It is difficult to evaluate the effect on the ulcers of sulphur injected intramuscularly, for typhoid vaccine was given intravenously and local applications were also used in most of the cases. In two cases of thromboangiitis obliterans with gangrenous ulcers, in which courses of vaccine were administered, the condition of the ulcers improved after the first injection of sulphur and the lesions were healed in three weeks.

In five cases of thromboangiitis obliterans, with severe ulcers or gangrene, the course of the disease was

unmodified by treatment with vaccine and sulphur, and amputation was necessary. Five patients were spared amputation. In one case of arteriosclerosis of the extremities, amputation was later necessary. The condition of one patient improved sufficiently to allow successful amputation of a toe, that of one patient was unchanged during a short period of observation. The ulcers on the heels of one patient with sclerodactylia healed slowly under treatment with combined sulphur and vaccine. In general, the results of injections of sulphur on ulcers or gangrene, in patients with peripheral vascular disease, were equal to and occasionally exceeded the results following intravenous injections of vaccine. The temperature of the skin increased following injections of sulphur in much the same manner as it increased following intravenous injections of vaccine.

THE METHOD OF ACTION OF INTRAMUSCULAR INJECTIONS OF SULPHUR

Mackay has reviewed the opinions as to the mechanism by which sulphur injected intramuscularly produces fever. Impressed by the theoretic nature of these opinions he approached the problem experimentally. Rabbits were used, but even with doses, based on body weight, which exceeded by thirty times those used in man, fever was not produced. Sections taken from the region injected, twenty-four and forty-eight hours after injection, gave evidence of profound necrosis and marked inflammatory reaction, large numbers of polymorphonuclear leukocytes and a few lymphocytes were present. Less striation of the

muscle fibers, with fragmentation and degeneration, was observed. Sections, taken thirteen days following injection, gave evidence of subsidence of the acute inflammatory process; there was evidence of proliferation of fibroblasts, and foreign-body giant cells and regenerating muscle fibers were seen. Olive oil was not essential to the production of the inflammatory reaction, for sulphur in a mixture of acacia, 1 per cent, in physiologic solution of sodium chloride produced the same pathologic changes as sulphur in olive oil. As a result of his experimental studies, Mackay expressed the belief that the fever which follows intramuscular injection of sulphur is a result of a reaction to protein liberated from the patient's own muscle, or that it is a result of the action of hydrogen sulphide formed from sulphur in the tissues. As Mackay logically pointed out, the afebrile period following injection, the increasing amounts of sulphur necessary, and the pathologic changes induced, argue for such a mechanism as was postulated by him.

COMMENT

The ideal pyrogenetic agent would be one which would produce fever of as long duration as is desired without disagreeable or harmful local or general reactions. Unfortunately such an agent is as yet unavailable. Intravenously injected vaccine, although a very valuable therapeutic aid, has the disadvantages that there is slight danger of complications, and that the fever is of comparatively short duration. Sulphur injected intramuscularly is superior to vaccine in that it can be used with safety for patients of advanced

age and in that the fever is of longer duration. It is inferior to vaccine because of its reaction and because of the distress occasioned at the site of the injection. The patient's attitude toward injection of sulphur varies; some patients request repeated injection because of favorable results; some extremely dislike, and nearly refuse, injection because of the pain induced.

Each patient should be informed of the pain before the injection is given, morphine or codeine should be used freely during the period of acute distress. Antipyretics, such as acetylsalicylic acid, should be avoided because of their effect in lowering temperature. As yet no permanent impairment of muscle function as a result of repeated injections has been reported even by Schroeder,^{13,14} who has had extensive experience. On the basis of Mackay's experimental work, such changes in muscle function can be reasonably expected provided injections are repeated a sufficient number of times. For our purpose, in the treatment of peripheral vascular disease, a smaller number of injections than that which Schroeder gave without detrimental effects is usually sufficient. Increasing doses were not necessary for one patient who received six injections.

The evidence that sulphur itself is of therapeutic value in peripheral vascular disease is largely lacking in this study. Because of the pain at the site of injection, the use of intramuscular injections of sulphur in the future probably will be reserved for persons to whom the distress is not severe, for those who are temporarily insensitive to typhoid vaccine, and for those of

advanced age. We cannot substantiate Mackay's observations that persons who do not respond well to vaccine do not respond to sulphur. Our experience is the opposite, and sulphur is commonly used when typhoid vaccine is ineffectual.

SUMMARY AND CONCLUSIONS

Observations were made on pain at the site of injection, on relief of pain in ulcerated or gangrenous regions, on healing of ulcers, on height and duration of fever, and on chill and leukocytosis in fifteen cases of peripheral vascular disease, in which thirty-two intramuscular injections of sulphur, 2 per cent, in olive oil were given. In five additional cases twelve injections were given, but detailed observations were not made.

Fever began about seven hours after the injection; the temperature reached an average maximal level of 102°F, and lasted an average of fifty hours. Chills occurred following approximately 50 per cent of the injections, but they were mild when doses of suspension of sulphur of 1.5 cc., or 2 cc., were given.

The most satisfactory dose in treatment of peripheral vascular disease was 1.5 c.c. or 2 c.c. Greater amounts were rarely necessary to produce effect even later in the course of the injections.

Clinical improvement was as marked following intramuscular injection of sulphur as that induced by intravenous injection of typhoid vaccine, and occasionally it was more striking.

The pain at the site of the injection varied from moderate to severe and constituted the greatest disability.

to intramuscular injection of sulphur in olive oil

Sulphur in olive oil, injected intramuscularly, in the treatment of peripheral vascular disease, is most satisfac-

tory for persons of advanced age, for those who are resistant to treatment by vaccine, and for those in whom the pain from the injection is not excessive

Mediastinal Displacement in Pneumothorax*†

By W C POLLOCK, M D, *Major, Medical Corps, U S Army*
Denver, Colorado

ROENTGENOLOGICAL study of pneumothoraces, whether artificially induced or spontaneous, frequently reveals mediastinal displacement. This displacement may be of the superior anterior mediastinum, of the inferior or of the entire mediastinum. The displacement associated with artificial pneumothorax therapy or in spontaneous cases is due to a disturbance of the normal physiological intrathoracic equilibrium. The degree of displacement is not in all cases proportionate to the change in intrathoracic equilibrium because of factors that will be discussed later.

Mediastinal displacement is observed in cases of pulmonary tuberculosis unassociated with pneumothorax and in cases where pneumothorax no longer exists, but this type of displacement will not be discussed in this paper.

The bulging or displacement of the superior anterior mediastinum is the type observed during fluoroscopic study of artificially induced pneumothorax cases. It is frequently noted during such study that the contra-

lateral lung is encroached upon by the pneumothorax cavity bounded by the mediastinal pleura. This condition is ordinarily detected only during fluoroscopic study and is not observed on the routine x-ray plate. As stated by Sewell¹ the bulging only eventuates during the phase of expiration and so far as it affects the respiration, it should operate to aid in the expiratory contraction of the lung and in the expulsion of its foul residual air. Conversely, the inspiratory swing of the mediastinum toward the middle line allows, if it does not assist, the renewal of air of unusual oxygenated power to the full capacity of the contralateral lung.

Mediastinal displacement of the type influenced by the phases of respiration in artificial pneumothorax is usually in right sided pneumothorax the mediastinal herniation or bulging invading the left chest. The reverse has been noted, but is a rather rare occurrence. When pneumothorax is induced on the left, the position of the esophagus obstructs mediastinal displacement from left to right. The displacement from right to left is possible because of an anatomical wedge between the two pleural cavities due to the fact that the aorta and compressed esophagus lie somewhat

*From the Medical Service, Fitzsimons General Hospital. Received for publication, March 3, 1931.

†This paper is one of the Surgeon General's Series which is not responsible for the views expressed or conclusions reached.

left of the vertebral column. Displacement does not occur in most cases because the mediastinum is fixed, or practically fixed, by adhesions and thickening of the pleura. This condition is frequently the case in older adults and in long standing cases of pulmonary tuberculosis, and for this reason mediastinal displacements are most frequently observed in earlier

cases of tuberculosis in younger adults where mediastinal mobility is not lessened by pleural thickening and adhesions.

Figure 1 illustrates the type of displacement under discussion, as shown on the x-ray plate. It is observed that the mediastinal pleura runs from the inner third of the clavicle downward to become continuous with the cardiac

FIG. 1

shadow at about the level of the third rib. As stated, routine x-ray plates seldom show the condition because they are usually made during the phase of inspiration, and during this phase the mediastinum moved toward the pneumothorax cavity. It is during fluoroscopy when the mediastinum can be observed, as to position, during inspiration and expiration that the apparent encroachment upon the contralateral lung is observed.

The condition is not a serious one and can hardly be classified as a complication. It is not associated with cardio-respiratory embarrassment. The encroachment as can be seen by lateral x-ray plates is not upon the lateral lung surface; but only upon its anterior surface. There is no lateral compression of the lung, but rather a slight anterior-posterior compression. The condition is of minor clinical significance and occurs in the presence of negative intrathoracic pressure.

Infrequently there is observed a superior anterior mediastinal displacement of an entirely different character. The right upper lobe of the lung herniates into the left chest, the hernial sac consisting of the mediastinal pleura. The hernia remains fixed in the left chest uninfluenced by respiration. There may be present respiratory embarrassment with a pressure sense to the stage of discomfort and the condition is considered of clinical significance. This condition is usually associated with positive pressure in the pneumothorax cavity of the right chest.

Figure 2 shows a hernia of the right upper lobe of the lung into the left chest. The plate is made during full expiration yet the hernia en-

croaches upon the contralateral lung. Respiration produced no movement of the hernia. The mediastinum, except for the anatomically weak superior anterior mediastinum, was relatively fixed. The plate is of a patient who received a refill of gas in an eastern city prior to journeying to Denver, Colorado. The eastern city being near sea level and Denver being over five thousand feet in altitude, it is estimated that the intrathoracic pressure was increased approximately twenty per cent. The increase was sufficient to produce a moderately high positive intrathoracic pressure which was sufficient to push the firm fibrous right upper lobe into the anatomically weak area of the mediastinum. Ordinarily mediastinal bulging occurs in cases where the pleura is relatively free and elastic, but as pointed out by Dummerst and Brette² it may occur in cases with relatively nonelastic pleura when there is overstrong pressure in the pneumothorax cavity.

In this case the mediastinum must have been relatively nonelastic and fixed since the case is one of long standing pulmonary tuberculosis in an adult 42 years of age. Artificial pneumothorax had been used as an adjunct in his treatment for over one year. There were numerous band-like adhesions over the lower half of the lung and at autopsy there was found one fibrous adhesion running from the visceral pleura to the mediastinal pleura.

In general, the degree of displacement depends upon flexibility of the mediastinum, the amount of intrathoracic pressure in the pneumothorax

space and the relative fixation of the mediastinal contents

The factor of importance in this case was that of intrathoracic pressure. The removal of 800 c.c. of air from the right chest completely reduced the herniation of the lung with considerable reduction of the cardio-respiratory embarrassment. During fluoroscopy

the mediastinal line could not be observed in the left chest, even during forced expiration.

Figure 3 shows the change produced by removal of air. The right upper lobe of the lung can now be seen in the right chest. The right lung has re-expanded somewhat, causing an elevation of the fluid level and the

FIG 2 Hernia of right upper lobe into the left chest

mediastinal bulging into the left chest through the anterior superior mediastinum no longer exists

We wish to emphasize the fact that such a condition is entirely different from the swinging superior mediastinum noted in young adults earlier in the employment of pneumothorax.

In this case the mediastinal hernia contained a lobe of the lung from the opposite chest with a sufficient encroachment upon the contralateral lung to cause respiratory embarrassment. The hernia did not recede during inspiration and did not increase its encroachment during expiration;

Fig. 1. Mediastinal hernia containing a lobe of the lung from the opposite chest.

therefore it hindered oxygenation of the contralateral lung

As stated by Stivelman, Hennell and Golembe³ the size of the untreated hemithorax will be proportionately decreased and because of this its intrapleural pressure will be proportionately less negative. The intrathoracic pressure on the untreated side will be proportionately increased and will be equal to the intrathoracic pressure on the pneumothorax side minus the elastic recoil of the stretched mediastinum.

In our case under discussion the decrease in negative pressure of the untreated hemithorax was greater than usually observed because of the ab-

sence of an elastic recoil of the mediastinum.

A similar case is shown by figure 4. In this case there is also an actual hernia of the lung through the superior mediastinum. The plate is of a case of a closed spontaneous pneumothorax superimposed upon an artificial pneumothorax. Figure 4a shows the specimen removed at autopsy. The portion of the lung invading the opposite chest stands out as distinct protrusion from the rest of the lung.

In cases with a relatively mobile mediastinum there may exist a marked degree of displacement without aggravating cardiorespiratory embarrassment. In the absence of pleuoperi-

FIG 4 Hernia of lung through the upper mediastinum

cardial adhesions the heart may be converted into a complete dextrocardia without cardiac symptoms. We are now referring to the type of mediastinal displacement in which the entire mediastinum and its contents are pushed to one side. This condition is observed in spontaneous pneumothoraces with positive pressure, usually associated with pleural exudate. Whether or not there are acute symptoms depends somewhat upon the rapidity of the displacement. If the lung collapse is rapid in a case untreated by pneumothorax the symptoms are usually acute. Should the spontaneous

pneumothorax be superimposed upon a previously existing artificially induced pneumothorax the symptoms may be extremely mild. In fact, the accident may happen and be unknown to the patient or his physician until it is detected by fluoroscopy prior to a contemplated pneumothorax refill. Apparently this type of displacement may occur to the right as well as to the left. However, the left to right displacement requires greater pressure and the degree of displacement is less.

Figures 5 and 6 show this type of displacement. These plates are of spontaneous pneumothoraces superim-

posed upon induced pneumothoraces, both showing pleural exudate. Both cases are of long standing and have few symptoms when the pleural exudate is removed at frequent intervals.

It has been noted in the earlier thoracenteses of such cases that the mediastinum returns to a practically normal position. Later in the treatment the mediastinum tends to become fixed in its displaced position and

shows little tendency to return to its normal position after removal of pleural exudate. The same is true of the swinging movement of the mediastinum during respiration which also tends to become less and less and finally may become fixed. As the mediastinum becomes fixed in the opposite chest there then appears more respiratory embarrassment and sensation of pressure, relieved by removal of air with return of the mediastinum to nor-

FIG 5 Displacement produced by spontaneous pneumothorax superimposed upon induced pneumothorax, with pleural exudate

mal position In these two cases the lung remained collapsed because of a small bronchial fistula which existed for some time without infection of the pleural exudate Bronchial fistulae were proven to exist by the introduction of dye into the chest cavity and noting same to appear in the sputum

This type of case sooner or later becomes a surgical case because of the development of pyothorax In some

instances in which the fistula is small and tortuous and requires coughing attacks to force air from the respiratory tract to the pneumothorax space, there may be considerable interval before the pleural exudate becomes infected

Another type of mediastinal displacement is the respiratory deviation of the entire mediastinum noted during fluoroscopy. This deviation, when

8-19-30

6072

observed during forceful respiration, is rather astounding in some cases. It is believed that many who have not given particular attention to movements of the mediastinum would be rather surprised to note the degree of respiratory deviation in certain cases. The mediastinum in instances seems to encroach upon the contralateral lung to over one-half of its diameter. An observer may in haste conclude that this type of displacement is the factor

of respiratory embarrassment. However, rather marked displacement is frequently seen in cases without symptoms. Let us again point out, as is shown by figures 7 and 8, the position of the mediastinum with reference to the phases of respiration. It will be noted that the mediastinum makes its encroachment upon the contralateral lung during the phase of expiration and recedes to the pneumothorax side on inspiration. Marked deviation is

FIG 7 Mediastinal relations during inspiration

usually observed in younger adults earlier in the treatment by artificial pneumothorax. It has also been observed that as pneumothorax treatment is continued the mediastinal mobility tends to become less and less, finally becoming relatively fixed. This is due to the fact that the pleura becomes less elastic, and somewhat thickened under continuous pneumothorax treatment. Von Muralto¹ calls attention to the positive assistance given the respiratory

function of the contralateral lung by the mediastinal deviation in therapeutic pneumothoraces. He also states that the situation here is the exact opposite to that found in wide open pneumothorax both as to mechanics and vital effects.

In cases of mediastinal deviation so well observed during respiration at the time of routine fluoroscopy there also exist characteristic manometer readings. The mediastinum is so flexible

that it is gradually displaced by the introduction of air into the pneumothorax cavity. This fact was discussed by Parfitt.¹ According to Boyle's Law, "The temperature remaining the same, the volume of a given quantity of gas is inversely as the pressure which it bears." This would mean that with rigid pneumothorax cavity walls there should be a proportionate change in the manometer reading following the introduction of each 100 c.c. of gas. It is not unusual, however, to observe that the manometer reading may show little change during the introduction of the first several 100 c.c. of gas. The interpretation of this is that the introduction of gas does not proportionately increase the pressure because the pneumothorax cavity has enlarged by mediastinal displacement.

Dumarest and Brette² state that disturbance of the mediastinum and the delicate organs it encloses causes functional trouble, such as dyspnea on exertion, and tachycardia uncomfortable for the patient, and may lead to a displacement of the mediastinal partition without pulmonary compression being either complete or effective.

We know that rather marked deviation may occur without symptoms. There must be other factors than the displacement in itself which result in functional trouble.

With an elastic mediastinum, free of adhesions, in the young adult, where the pressure in the pneumothorax cavity is maintained well on the negative side there are usually no symptoms resulting from mediastinal deviation.

The most pronounced symptoms have been observed in left pneumothorax with pleuro-pericardial adhesions, and in longer standing cases with thickened pleura where pressure is employed to stretch adhesions for better collapse of cavitations. It has been our experience that functional symptoms are more apparent where pressure is applied to a relatively fixed mediastinum than where there is considerable deviation of a flexible mediastinum under negative pressure.

The movements of the mediastinum are called, by Stivelman, Hennell and Golembe³ "Movements of Balance." They state that the intrathoracic pressure is established in pneumothorax as under all normal conditions. The change in pressure in one hemithorax must be balanced by approximate changes on the opposite side, and it is in response to this fundamental principle that certain so-called "Movements of Balance" take place in the chest cavity in pneumothorax.

When both hemithoraces are exactly alike in capacity and both lungs are equally expanded to fill them, there would be comparatively little or no disturbance in the relative position of the mediastinum during inspiration. On the other hand, supposing one hemithorax to be relatively immobile and the other hemithorax capable of large expansion, we can easily see how, during inspiration, a movable mediastinum would be shifted toward the large hemithorax because of the rapidly increasing negative pressure developed therein. It is believed that some understanding of the so-called "Movement of Balance" in pneumothorax is essential. The physics of

the phenomenon may upon superficial consideration appear rather confusing, but when one fully appreciates that we are dealing with differences in pressure and that the pressure changes with the phases of respiration, the movements noted under the fluoroscope are then understood. In fact, the phenomenon becomes simple. Appreciation of such movements leads to a clearer understanding of Kienboeck's phenomenon and other forms of paradoxical breathing.

We have been unable to demonstrate true paradoxical diaphragmatic breathing in artificially induced pneumothorax. The diaphragm has been noted to be lower than normal, may appear irregular in passing from the phase of expiration to inspiration and may appear to present a paradoxical movement of slight amplitude when the intrathoracic pressure on the pneumothorax side reaches a positive pressure at expiration. The apparent paradoxical movement disappears when the pressure is decreased or when position of the patient is changed toward the pneumothorax side.

True paradoxical diaphragmatic breathing is observed in pneumothorax cases when there is a paralysis of the diaphragm.

With the principle of "Movements of Balance" in mind an attempt was made to determine the approximate degree of incapacity of respiratory movement of the hemithorax required to produce movements of balance. Immobilization of the hemithorax by fixation of chest wall in a normal individual caused no movement of the chest. Fixation of the chest wall in a patient with a paralyzed hemithorax

increased movement of the diaphragm. To prevent compensatory diaphragmatic breathing on the side of fixation, an individual was selected who had a paralyzed diaphragm due to phrenic exeresis. The individual selected showed a movement of the mediastinum during forced respiration. The right chest was immobilized, and x-ray made during full inspiration and another during full expiration, with the result that the mediastinum was found to remain practically stationary. The cardiac shadow was found to move through a distance of only nine-tenths of a centimeter.

It was found that procedures as outlined above were insufficient to produce mediastinal movements as frequently observed in artificial pneumothorax cases where lung compression ranges from twenty-five to fifty per cent.

SUMMARY

A disturbance of the normal physiological intrathoracic pressure during the course of artificial pneumothorax therapy may produce mediastinal displacement when the mediastinum is sufficiently flexible.

Mediastinal displacements extending into the contralateral lung during the phase of expiration are of no clinical significance. However, fixed displacements in the presence of a relatively nonelastic mediastinum are produced by over strong pressure. The pneumothorax cavity may give rise to respiratory embarrassment in the sense of pressure to the stage of discomfort. A reduction of the displacement results in comfort to the patient. Mediastinal displacement is

upon flexibility of the mediastinum, the intrathoracic pressure in the pneumothorax cavity, and the relative fixation of the mediastinal contents

usually occurs in younger adults early in artificial pneumothorax treatment, and the mediastinum tends to become less and less flexible as pneumothorax therapy is continued

A relatively flexible mediastinum

Treatment of Recurrent Erysipelas*

By HAROLD L. AMOSS, M D, F A C P, *Durham, N C*

RECRUDESCENCES and relapses are not uncommon in streptococcal infections. In facial erysipelas, the lesion may subside and the skin become almost normal but suddenly within a few hours all the signs and symptoms may return. When this occurs in facial erysipelas we have learned to suspect the presence of sinusitis. An example will illustrate this type of recrudescence.

Italian girl, aged sixteen years, admitted on the sixth day of an erysipelas infection involving both sides of the face, marked cervical adenitis and pharyngitis with obstruction to breathing. There was tenderness over both maxillary sinuses.

The symptoms of toxemia disappeared quickly after the administration of erysipelas antitoxin and the lesion began to recede but the fever did not abate for three days and then endured to a mild degree. Ten days later, both maxillary sinuses were irrigated and from the pus there was obtained a pure culture of beta hemolytic streptococci. The temperature came to normal and later rose presaging severe serum sickness. Suddenly on the twenty-seventh day after onset, the patient complained of chills, sensations and headache and the temperature rose to 104°F. There was a rapid return of the lesion confined strictly to the areas previously involved but the skin was less shiny. The leukocyte count rose rapidly from 8000 to 15000. The tonsils and cervical glands were not noticeably enlarged or tender. The nasal

passages were completely stopped by dried mucosanguineous discharges. After shrinking and the removal of a large amount of bloody pus by suction, the patient felt much improved, the temperature fell sharply to normal within four hours, and within eight hours the erythema and swelling of the face had disappeared. The leukocyte count became normal in twenty-four hours. Eighteen hours later the succession of events was repeated exactly, and the patient was discharged well, eight days later and has remained so for one year.

In other cases, treated with serum the skin previously involved and showing almost complete return to normal may become red, tender and swollen but not thick and brawny. Because of general glandular enlargement, arthritis and urticaria in other parts of the body and the failure in every case to cultivate streptococci from the skin, and also the subsidence of the lesion and the general signs, we regard this apparent recrudescence as a manifestation of serum sickness.

There is still another type of true recurring erysipelas in which the typical signs and symptoms recur after several months or years. Usually the succeeding attacks are milder than the first but recurring erysipelas may be severe and attacks vary in intensity. We have studied 25 such cases in the Danville State Hospital for the Insane. In eight of these patients there was no reaction to the endermal injection of 0.1 cc. of

*Presented at the 1934 Meeting of the American College of Physicians, March 1934.

trate of the broth culture of the erysipelas hemolytic streptococci. Of the remaining 17, three died of other causes during the year of observation. There remained 14 patients who had experienced from 2 to 5 attacks of erysipelas during the preceding two years and who, at the beginning of the study, reacted to one or more of the test strains. Without varying any other factor these 14 patients were given subcutaneously increasing doses of the streptococcus filtrate and tested for sensitivity every six months for two years. Ten patients reacted to both allergins. Further immunization with the second allergin reduced the sensitivity in all but three of them. Thus three patients remained sensitive and of these, two had a mild recurrent attack of erysipelas during the two years of observation.

In summary 14 patients had 35 attacks of erysipelas in the two years before the immunizing experiment but among the eleven patients surviving the two years of observation and immunization there occurred only two attacks of erysipelas. Apparently the injection of streptallergen in these patients had a decided effect on the number and intensity of the recurring attacks.

The main purpose of this paper is to describe our experiences in a third type of so called recurrent erysipelas of the leg. These cases really belong to the category of cellulitis. As a preface to a description of chronic recurring cases there will be presented an acute case which initiated the reasoning approaching the allergic concept.

Case I Italian, male, 28, toes crushed. With dressings, the superficial lacerations

healed in six weeks and the patient was ambulant for ten days. Suddenly, four days before coming to us, the dorsum of the foot became swollen, hot and painful, and with a high fever, the patient experienced chills, nausea and anorexia. He was admitted to the ward with cellulitis of the foot and leg, femoral and inguinal adenitis. The symptoms had increased. He was given intravenously and intramuscularly erysipelas antiserum. Within ten hours, the temperature was normal and the lesion began to recede so that within three days it had entirely subsided. Beta hemolytic streptococci were obtained in pure culture from a fluctuant tumor on the under surface of the second toe and from the skin lesion on the leg. The abscess on his foot healed slowly and the patient was discharged six and a half weeks after admission, as well. Four days later he noticed a slight and offensive discharge from about his toes on both feet but there were no constitutional symptoms. He walked without discomfort and seemed well for one month when he lost his appetite and felt unable to work. Four days later, he had suddenly a chill and within a few hours, the swelling, redness and pain appeared in the area previously involved. He was readmitted with a temperature of 103.6°, WBC 19,000, and presented a picture practically identical to that of the previous admission, except that the skin over the involved area was a darker red. Cultures at this time were positive from the recurring abscess under the second toe but skin cultures from the involved area were negative. The abscess was drained and temperature became normal and the redness, swelling and tenderness of the skin of the leg disappeared completely. The patient has remained well.

At that time, it did not occur to us to compare the reactivity of the skin over the involved area to injections of toxic filtrates. But as the uninvolved skin was very reactive, he was used to test several fractions so that he received fourteen endodermal injections. When tested two months after discharge, the skin of the involved area was less re-

active than uninvolved areas. This is in accord with subsequent experience in a number of cases.

In the chronic recurring cases the lesion usually involves the lower leg which becomes swollen tender and intensely red. The skin usually remains thin and blanches on pressure but here and there are outcroppings of a true erysipelatous aspect in which the skin itself is brawny, is not blanched by pressure and blebs form. The dorsum of the foot may or not be involved but often the entire foot may be swollen. There is usually femoral adenitis and general symptoms such as fever, chills, tachycardia, anorexia and headache. The recurrences which may appear after an interval of two weeks or six months are usually ushered in by the general symptoms of which the first sign may be fatiguability or sudden chill. The patients recognize immediately by these symptoms that another recurrence is imminent. They remain in bed for five days to two weeks and seem perfectly well between the attacks.

The following case history in abstract will illustrate this type of infection—

H. R. W., white man, aged 39 years, admitted September 24, 1927. Except for frequent colds up to four years ago when the sinuses were drained and tonsils enucleated, the patient enjoyed excellent health.

September 7, 1926 he suddenly experienced chill and high fever. His left leg became red, swollen and quite painful from the ankle to a line 7 cm. below the knee. A diagnosis of erysipelas was made. At operation was found to be a simple cellulitis. The attack subsided. He recovered the previous day. On January 1, 1927, a second attack occurred. The leg was again swollen and red. The attack subsided. He recovered the previous day. On January 1, 1927, a third attack occurred. The leg was again swollen and red. The attack subsided. He recovered the previous day.

fection of the same leg which lasted for other two weeks. Since then there have been four more recurrences as follows:

Second attack January, 1927, two weeks duration.

Third attack April, 1927, eight days duration, right leg also involved.

Fourth attack June, 1927, two weeks duration.

Fifth attack July, 1927, three days duration.

Sixth attack August, 1927, two weeks duration.

He felt well between attacks and in spite of five attacks in eight months gained 13 pounds in weight.

September, 1927. The general physical examination revealed nothing abnormal. Laboratory tests added nothing of importance. Cultures of the nose and throat failed to demonstrate streptococci or any other predominating organisms.

Between the toes on both feet, however, an epidermophyton infection was discovered, identified microscopically but not cultivated.

To determine sensitivity to several of the streptococcus filtrates, he was tested on September 29, 1927, by endodermal injections of C strain and B strain filtrates both on the leg and on the arm. He was positive to both; the reactions were more marked on the legs. On October 1, immunization was started by gradually increasing doses of B filtrate subcutaneous. He was tested again to the toxic filtrates on November 26 (one and a half months later) when it was found that he did not react to B filtrate (used in his immunization) but still remained markedly positive to C filtrate. The reaction was more marked on the arm than in the area of the leg which had been affected. The patient has gained 20 pounds and feels well. He has applied dusting powder to the toes after washing them in warm water and alcohol twice daily. The itching of the legs which previously had been severe enough to keep him awake, has disappeared.

Skin test applied to the dorsum of the arm from the strain of erysipelas recovered as follows:

The control consisted of 0.1 cc of 1 to 100 tryptic broth				
Date	Area tested	Filtrate	Reaction	Control
Sept 29	left arm	Filtrate B	++	0
		Filtrate C	++	
	left leg	Filtrate B	+	
		Filtrate C	++	

Subcutaneous injection of increasing doses of B filtrate were made at five-day intervals from October 10 to November 21

Date	Area tested	Filtrate	Reaction	Control
Nov 26	left arm	Filtrate B	±	0
		Filtrate C	+++	
	left leg	Filtrate B	0	
		Filtrate C	+	

From November 26 to February 5, at five day intervals increasing doses of C filtrate were injected subcutaneously. Tests were made again on May 19, 1928. The skin of the arm and leg reacted to filtrate of strain C but not to filtrate B. The reactions were more intense on the arm than on the leg.

This patient has had no recurrence in 3 1/2 years.

Two points in this abstract form the basis of our present method of treating such patients.

1) The skin on the affected side when tested during the interval between attacks, reacted to a greater degree to the endermal injection of the streptococcus filtrate (so called strept-allergin) than the skin of the other leg, or of the arm. A course of injections of gradually increasing doses of the streptallergin was followed by the state of nonreactivity earlier in the affected area than in the other leg. Because of this fact it may be assumed that the skin over the involved area was in a state of hypersensitivity. The involved area has not been more reactive in but 15 of the 23 cases tested, but in every patient there was a marked reaction. The tentative hypothesis that the lesion is an allergic response is supported also by the fact that in no instance has it been possible to cultivate hemolytic streptococci from skin puncture. It has been shown by biopsy that a few organisms are pres-

ent (culture) yet they are sparsely scattered in small nests throughout the tissues.

2) The second point is the presence of a break in the skin between the toes on the affected side from which epidermophyta were seen in the scrapings. In some cases they have been cultivated. In every case there has been a fungus infection on one or both feet and when the lesion is visible on only one side it is invariably on the side on which the recurrent cellulitis appears.

In four cases hemolytic streptococci have been obtained from culture of the debris removed from the edge of the toe nails.

The plan of the treatment is as follows — The skin at symmetrical points on the legs is tested for sensitivity by the injection of 0.1 cc of 1-100 filtrate from 6 stock strains. The strain provoking the greatest reaction is used as the desensitizing agent. Increasing doses of 1-100 dilution are given at five day intervals usually doubling the dose each time. The process is then continued with 1-10 and finally with the undiluted filtrate. After 5 doses of 1 cc of the undiluted filtrate the areas are again tested and if the reaction zone measures over 1 cm at 24 hours the injections are continued with

the filtrates which provoke reaction

Inasmuch as it is probable that the fungus infections open the way for the entrance of the streptococci, efforts are directed toward the removal of this very resistant infection. The routine procedure is as follows—

Whitfield's ointment, which is a 5 per cent salicylic acid salve is reinforced by the addition of 1 per cent thymol iodide and applied each night. After cleansing with soap and water the next morning the skin between the toes and of the soles of the feet is wiped from 70 per cent alcohol and a 1 per cent solution of thymol iodide in 70 per cent alcohol is applied and allowed to dry. A dusting powder of the following composition is used.

Salicylic acid	5
Thymol iodide	1.
Boric acid	
Starch aa	50

and when the socks are changed at 5 P M the affected areas are cleaned as in the morning. Soiled socks are boiled as soon as possible after removal.

Among the 23 patients treated (of whom 3 are still under observation) there have been no recurrences. The longest period of observation is 3½ years. In two other cases of recurring lymphangitis following burns with extensive scarring the treatment seems to be little value.

The 23 patients studied have come from the several states: two from New York, two from Texas, one from California and the remainder from the South Atlantic States.

It is possible that the immunizing process is not necessary. Perhaps the care of the feet is the essential point and it is recommended that this be tried first.

The Historical Development of the Present Conception of Cardiac Conditions in Exophthalmic Goiter*

By A MORRIS GINSBERG, A B , M D , F A C P , *Kansas City, Missouri*

ALLOW your imagination to wander back five hundred years and picture a medieval castle upon a mountain top. Note how it stands majestically, a towering and commanding edifice. You might compare this castle to the thyroid gland, standing as it does at the top of human emotions and commanding its every act. It is then, and then only, that you are able to appreciate this small but "mighty" organ whose symptoms are expressed in practically every tissue in the body. The thyroid gland may be responsible for symptoms manifested in the skin, blood, bones, joints, muscles, the lymphatic glands, the nervous system, the gastrointestinal system, the genito-urinary system, the metabolic system, the endocrine system and, probably most conspicuously, in the cardiovascular system. It is, indeed, important to remember that these distant areas may first call the attention of the alert physician to pathology of the thyroid gland. All grades and variations of these referred symptoms are experienced and, I am sorry to say, it is not rare for even the mature doctor of note to miss the diagnosis. In other words, I desire to emphasize

the fact that we must remember that, although thyrotoxicosis is a localized disease of the thyroid gland, it has myriads of generalized symptoms which may be manifested anywhere from the head to the toes.

These distant symptoms may precede for months any enlargement of the thyroid gland and it is not unusual to encounter cases which *never* show any thyroid enlargement whatsoever.

Fate is a trickster and often barely misses making an individual immortal. Such was the case with the Bath physician, Caleb Hillier Parry,¹ who described exophthalmic goiter, as we know it today, fifty years before either Graves or von Basedow discovered the symptom complex. Osler often said that Parry should be given credit for having first clearly described hyperthyroidism. Not only did he describe this disease but he was the first to call attention to the symptoms referable to the heart. This was in 1786. I shall quote his first case:

"There is one malady which I have in five cases seen coincident with what appeared to be enlargement of the heart, and which, so far as I know, has not been noticed, in that connection, by medical writers. The malady to which I allude is enlargement of the thyroid gland."

*Received for publication April 25, 1931

"The first case of this coincidence which I witnessed was that of Grace B., a married woman, aged thirty-seven, in the month of August, 1785. Six years before this period she caught cold in lying-in, and for a month suffered under a very acute rheumatic fever, subsequently to which, she became subject to more or less of palpitation of the heart, very much augmented by bodily exercise and gradually increasing in force and frequency till my attendance, when it was so vehement, that each systole of the heart shook the whole thorax. Her pulse was 156 per minute, very full and hard, alike in both wrists irregular as to strength, and intermitting, at least once in six beats. She had no cough, tendency to fainting, or blueness of the skin, but had twice or thrice been seized in the night with a sense of constriction and difficulty of breathing, which was attended with a spitting of a small quantity of blood. She described herself also as having frequent and violent stitches of pain about the lower part of the sternum.

"About three months after lying-in, while she was suckling her child, a lump of about the size of a walnut was perceived on the right side of her neck. This continued to enlarge till the period of my attendance, when it occupied both sides of her neck, so as to have reached an enormous size, projecting forwards before the margin of the lower jaw. The part swelled was the thyroid gland. The carotid arteries on each side were greatly distended, the eyes were

morning and often threw up fluid tinged with bile.

"She nursed for a year the child of her first lying-in, during which time she did not menstruate. Subsequently to that period she had five times miscarried, and for the last four months her menses had been irregular as to intervals and defective in quantity and colour. Bowels usually lax and more especially so for the last three weeks. It was directed that six ounces of blood be taken from her arm and that she should take twice a day, a pill consisting of dried Squill and quicksilver triturated with Manna, of each, one grain.

"The bleeding almost immediately relieved the dyspnea and stitches across the sternum. But the edematous swellings were increased and the urine did not exceed half a pint in twenty-four hours. She had been purged seven or eight times each day. Her pulse was 114, full and hard, and never more than six strokes without intermission. This was the state of symptoms on the sixteenth of August. The bleeding was ordered to be repeated and the pills to be continued.

"I did not again see her till the twenty-fifth when she had taken eight of the pills, which did not affect the mouth, but had produced seven or eight watery stools daily. The urine, however, did not amount to three ounces in the twenty-four hours and was very high colored and extremely turbid on standing, with a copious sediment. Her drink was about a quart in the day. Each systole of the heart shook the whole trunk

Graves⁴ described the syndrome. In 1840, Von Basedow⁵ called attention to the triad of goiter, cardiovascular symptoms and exophthalmus. In 1863, Potain⁶ contributed a clinical discussion to the subject. The same year Trousseau⁷ used tincture of iodine instead of tincture of digitalis by mistake on a toxic thyroid heart and, when he discovered his error and stopped the iodine, the heart condition was made worse. In 1878, Rose⁸ first emphasized the importance of the heart in sudden deaths of patients with goiter. He felt it was due to a mechanical factor. In 1879, Lockridge⁹ wrote about this disease and wished to name it "Cardiac Exophthalmic Goiter." Others, at this time, reported cases which they believed to be very much influenced by nervous factors. In 1896, Mobius¹⁰ emphasized the importance of tachycardia, palpitation, forceful beating of the heart and the arrhythmia in these cases of thyroid disease and stated that exophthalmic patients "suffer and die through their hearts, practically always is the condition of the heart important." In 1899, Kraus¹¹ was the first to suggest the toxic theory of exophthalmic goiter. It was Kocher¹² who said that he believed the surgeon should be guided by the cardiac condition in choosing the time and the extent of the operation and that there were probably no cases of exophthalmic goiter in which cardiac symptoms were completely wanting.

As we come down to the present time, we find the pendulum is swinging to the opposite side. We hear authorities such as Willius, Boothby and Wilson^{13,14} say that "the most out-

standing fact is the infrequency in both exophthalmic goiter and adenoma with hyperthyroidism of symptoms indicating cardiac disease." Hurxthal¹⁵ states that there is "no evidence that thyrotoxicosis injures normal healthy hearts because there is very little, if any, evidence of damage in cases under forty." Too, Lahey and Hamilton¹⁶⁻¹⁹ write that "young individuals with previously undamaged hearts suffer no cardiac changes, no matter how intense the toxicity."

How are we to reconcile our clinical findings with these recent statements?

Let us for a moment turn to the pathological and experimental data at hand. Wilson²⁰ in eighteen cases of hyperthyroidism found that the myocardium showed "swollen fibers with indistinct striations and well-marked lipid changes." Only five patients were under forty. He further states "that in patients with long-continued pronounced hyperthyroidism the myocardium shows more-advanced fat-changes than are present in the myocardium of individuals of the same age without hyperthyroidism."

Fahr²¹ described two patients who died of heart failure following partial thyroidectomy. He found an interstitial myocarditis with an accumulation of round cells between the muscle fibers and in the neighborhood of small vessels, as well as degenerative changes, such as fragmentation and destruction of muscular fibers. He further described three other patients with hyperthyroidism who also showed at autopsy, small round cell infiltration, fatty degeneration and hyaline focal necrosis.

Goodpasture²² had two cases with auricular fibrillation who died of myocardial exhaustion. One showed a focal necrosis of the myocardium and the other an extensive necrosis. However, these two patients had pathology other than the hyperthyroidism which could account for the myocardial necrosis.

More recently, Thomas²³ reports a case of exophthalmic goiter with cardiac decompensation, who died on the third day. He found a slight increase in connective tissue about a few blood vessels, a slight infiltration of polynuclears and mononuclears between the strands of fibers. The cause of death of the patient, however, was a coronary thrombus. He reports an exophthalmic goiter patient with cardiac decompensation and auricular fibrillation of more than a year's duration, who made such a complete recovery that he felt that severe intoxication certainly need not produce permanent cardiac damage.

Hashimoto²⁴ examined two hearts from exophthalmic patients and found "lymphocytic infiltration between muscle fiber or around blood vessels."

These reported cases are too few to permit us to form a definite opinion.

Goodpasture²² fed rabbits thyroid extract and thyroxin and found "slight but definite lesions in the myocardium, notably perivascular necrosis or fibrosis in the wall of the right ventricle, perivascular or fibrosis in the papillary muscle of the left ventricle and a moderate to severe focal necrosis in the myocardium adjacent to the wall." When the thyroid extract was fed to dogs, the results were similar. He also reported that the thyroid extract fed to dogs resulted in a moderate to severe focal necrosis in the myocardium adjacent to the wall.

to the conclusion that "hearts overstimulated by disease of the thyroid and laboring in a condition bordering on exhaustion were in a state of greater susceptibility to injury by toxic substances, such as may have resulted from a relatively mild terminal infection which, under other circumstances, might not have injured the myocardium." This conclusion is certainly well-worth remembering. Tonsillectomy or pulling of the teeth, in such a patient, may bring disastrous results.

Hashimoto²⁴ produced experimental myocarditis in animals with toxic doses of dried thyroid substances and found interstitial tissue lesions not unlike the Aschoff nodules in acute rheumatic fever and when the lymphocytic infiltration was increased it caused disintegration and destruction of muscle fibers. The hearts of these animals showed enlargement.

Farranti²⁵ found in the hearts of thyroid-fed cats and rabbits swollen muscle fibers with few nuclei and no transverse striations. Iscove-co²⁶ found that repeated injections of thyroid extract produced, in rabbits, hypertrophy of the heart. Other organs such as suprarenals, ovaries, uterus, spleen and kidneys shared in this enlargement. Hoskins,²⁷ Herring,²⁸ Hewitt²⁹ and others³⁰ obtained similar results, namely: hypertrophy of the heart and hypertrophy of the other organs. Experiments by Simonds and Brandes³¹ who fed desiccated thyroid to dogs resulted in further proof that there is actual hypertrophy of the heart.

Certainly the experimental feeding of thyroid cannot be ignored.

Does the heart have more susceptibility to injury by toxic substances, such as may have resulted from a relatively mild terminal infection which, under other circumstances, might not have injured the myocardium?

Sane³³ report an increased minute volume output of the heart in thyrotoxicosis and this increase is proportional to the increase in metabolism. The systolic output per beat of the heart decreases after thyroidectomy. Fullerton and Harrop³⁴ found a parallelism between the increase in basal metabolism and cardiac output per minute. Rabinowitch and Bazin³⁵ are the only ones who did not find an increased cardiac output in thyrotoxicosis. Robinson³⁶ studied a case of thyrotoxicosis and found that the cardiac output was actually increased to a greater degree than the oxygen consumption of the body. This means that, in this disease, there is a constant extra load imposed on the heart. In this particular case, Robinson found after thyroidectomy that the minute output fell from 10,000 cc to 3,890 cc, while the metabolism fell from plus 58 to plus one. This gives us some idea as to the great amount of work the heart does in thyrotoxicosis. Burwell and his coworkers³⁷ found a definite increase in cardiac output in thyrotoxicosis.

What are the subjective symptoms referable to the cardiovascular system in thyrotoxicosis? At the outset, let me state that there is little difference in the cardiac disturbances, between exophthalmic goiter and the adenoma with secondary hyperthyroidism. It must be remembered, however, that exophthalmic goiter is usually found in much younger individuals than is adenoma with hyperthyroidism. For that reason, we must expect physiologic changes in the cardiovascular tree in these older patients

with adenoma and secondary hyperthyroidism.

Probably the first symptom of which these patients complain is palpitation or being conscious of their heart action, usually brought on by mental or physical exertion of a mild nature. The sensation of pounding in the chest will naturally unnerve an already highly-nervous patient. Sometimes, there are attacks of palpitation of a paroxysmal nature and it is then that we suspect an irregularity. Soon these patients notice undue breathlessness or fatigue on the least exertion. It is not long, thereafter, that this dyspnea becomes more marked. The patient flushes freely and spasmodically on account of the great lability of the vasomotor system. A common complaint is the throbbing in the neck and a sense of tightness or constriction of it. Quite often distress over the precordia or a fullness in the chest may send the patient hurriedly to the doctor. This distress or fullness, even called pain by some, is not severe. There is no radiation of this discomfort and usually it is designated as being in the region of the apex or toward the anterior axillary line.

Upon *inspection*, we see increased carotid pulsation and flushing of the face and neck. The skin of the face, neck and upper chest has a salmon hue, hyperemic and somewhat pigmented. The peripheral vessels, too, may show increased pulsation. Capillary pulsations are frequently noted. Looking at the precordia, we note a forceful apex impulse which gradually increases its power and, as time goes on, the apex beat becomes diffuse and can be noted moving downward and outward.

"The first case of this coincidence which I witnessed was that of Grace B., a married woman, aged thirty-seven, in the month of August, 1786. Six years before this period she caught cold in lying-in, and for a month suffered under a very acute rheumatic fever, subsequently to which, she became subject to more or less of palpitation of the heart, very much augmented by bodily exercise and gradually increasing in force and frequency till my attendance, when it was so vehement, that each systole of the heart shook the whole thorax. Her pulse was 156 per minute, very full and hard, alike in both wrists—irregular as to strength, and intermitting, at least once in six beats. She had no cough, tendency to fainting, or blueness of the skin, but had twice or thrice been seized in the night with a sense of constriction and difficulty of breathing, which was attended with a spitting of a small quantity of blood. She described herself also as having frequent and violent stitches of pain about the lower part of the sternum.

"About three months after lying-in, while she was suckling her child, a lump of about the size of a walnut was perceived on the right side of her neck. This continued to enlarge till the period of my attendance, when it occupied both sides of her neck, so as to have reached an enormous size, projecting forwards before the margin of the lower jaw. The part swelled was the thyroid gland. The carotid arteries on each side were greatly distended, the eyes were protruded from their sockets, and the countenance exhibited an appearance of agitation and distress, especially on any muscular exertion, which I have rarely seen equalled. She suffered no pain in her head, but was much distressed with giddiness.

[illegible]

morning and often threw up fluid tinged
with bile

“She nursed for a year the child of her first lying-in, during which time she did not menstruate. Subsequently to that period she had five times miscarried, and for the last four months her menses had been irregular as to intervals and defective in quantity and colour. Bowels usually lax and more especially so for the last three weeks. It was directed that six ounces of blood be taken from her arm and that she should take twice a day, a pill consisting of dried Squill and quicksilver triturated with Manna, of each, one grain.

"The bleeding almost immediately relieved the dyspnea and stitches across the sternum. But the edematous swellings were increased and the urine did not exceed half a pint in twenty-four hours. She had been purged seven or eight times each day. Her pulse was 114, full and hard, and never more than six strokes without intermission. This was the state of symptoms on the sixteenth of August. The bleeding was ordered to be repeated and the pills to be continued.

"I did not again see her till the twenty-fifth when she had taken eight of the pills, which did not affect the mouth, but had produced seven or eight watery stools daily. The urine, however, did not amount to three ounces in the twenty-four hours and was very high colored and extremely turbid on standing, with a copious sediment. Her drink was about a quart in the day. Each systole of the heart shook the whole trunk of the body. The edema had extended itself nearly to the navel.

"The pills were repeated and she was ordered to drink freely of a solution of super-tartrate of Potash. From this time no further application was made to me respecting this patient who probably, soon paid her debt to nature."

In 1902 Flapan described a new disturbance in the behavior of the fish, which he called "the fish disease". It was characterized by a general loss of appetite, a general loss of energy, and a general loss of interest in the environment. The fish would not feed, and they would not move. They would just sit there and die. He called it "the fish disease" because it was a disease of the fish.

Graves⁴ described the syndrome. In 1840, Von Basedow⁵ called attention to the triad of goiter, cardiovascular symptoms and exophthalmus. In 1863, Potain⁶ contributed a clinical discussion to the subject. The same year Trousseau⁷ used tincture of iodine instead of tincture of digitalis by mistake on a toxic thyroid heart and, when he discovered his error and stopped the iodine, the heart condition was made worse. In 1878, Rose⁸ first emphasized the importance of the heart in sudden deaths of patients with goiter. He felt it was due to a mechanical factor. In 1879, Lockridge⁹ wrote about this disease and wished to name it "Cardiac Exophthalmic Goiter." Others, at this time, reported cases which they believed to be very much influenced by nervous factors. In 1896, Mobius¹⁰ emphasized the importance of tachycardia, palpitation, forceful beating of the heart and the arrhythmia in these cases of thyroid disease and stated that exophthalmic patients "suffer and die through their hearts, practically always is the condition of the heart important." In 1899, Kraus¹¹ was the first to suggest the toxic theory of exophthalmic goiter. It was Kocher¹² who said that he believed the surgeon should be guided by the cardiac condition in choosing the time and the extent of the operation and that there were probably no cases of exophthalmic goiter in which cardiac symptoms were completely wanting.

As we come down to the present time, we find the pendulum is swinging to the opposite side. We hear authorities such as Willius, Boothby and Wilson^{13,14} say that "the most out-

standing fact is the infrequency in both exophthalmic goiter and adenoma with hyperthyroidism of symptoms indicating cardiac disease." Hurxthal¹⁵ states that there is "no evidence that thyrotoxicosis injures normal healthy hearts because there is very little, if any, evidence of damage in cases under forty." Too, Lahey and Hamilton¹⁶⁻¹⁹ write that "young individuals with previously undamaged hearts suffer no cardiac changes, no matter how intense the toxicity."

How are we to reconcile our clinical findings with these recent statements?

Let us for a moment turn to the pathological and experimental data at hand. Wilson²⁰ in eighteen cases of hyperthyroidism found that the myocardium showed "swollen fibers with indistinct striations and well-marked lipid changes." Only five patients were under forty. He further states "that in patients with long-continued pronounced hyperthyroidism the myocardium shows more-advanced fat-changes than are present in the myocardium of individuals of the same age without hyperthyroidism."

Fahr²¹ described two patients who died of heart failure following partial thyroidectomy. He found an interstitial myocarditis with an accumulation of round cells between the muscle fibers and in the neighborhood of small vessels, as well as degenerative changes, such as fragmentation and destruction of muscular fibers. He further described three other patients with hyperthyroidism who also showed at autopsy, small round cell infiltration, fatty degeneration and hyaline focal necrosis.

Goodpasture²² had two cases with auricular fibrillation who died of myocardial exhaustion. One showed a focal necrosis of the myocardium and the other an extensive necrosis. However, these two patients had pathology other than the hyperthyroidism which could account for the myocardial necrosis.

More recently, Thomas²³ reports a case of exophthalmic goiter with cardiac decompensation, who died on the third day. He found a slight increase in connective tissue about a few blood vessels, a slight infiltration of polynuclears and mononuclears between the strands of fibers. The cause of death of the patient, however, was a coronary thrombus. He reports an exophthalmic goiter patient with cardiac decompensation and auricular fibrillation of more than a year's duration, who made such a complete recovery that he felt that severe intoxication certainly need not produce permanent cardiac damage.

Hashimoto²⁴ examined two hearts from exophthalmic patients and found "lymphocytic infiltration between muscle fiber or around blood vessels."

These reported cases are too few to permit us to form a definite opinion.

Goodpasture²² fed rabbits thyroid extract and thyroxin and found "slight but definite lesions in the myocardium, notably perivascular necrosis or fibrosis in the wall of the right ventricle, perivascular or fibrosis in the papillary muscle of the left ventricle and in the interventricular septum. Focal necrosis of the myocardium also occurred. When the thyroid extract was fed to normal rabbits, no definite lesions were observed." These results are in agreement with the results of other workers.

to the conclusion that "hearts overstimulated by disease of the thyroid and laboring in a condition bordering on exhaustion were in a state of greater susceptibility to injury by toxic substances, such as may have resulted from a relatively mild terminal infection which, under other circumstances, might not have injured the myocardium." This conclusion is certainly well-worth remembering. Tonsillectomy or pulling of the teeth, in such a patient, may bring disastrous results.

Hashimoto²⁴ produced experimental myocarditis in animals with toxic doses of dried thyroid substances and found interstitial tissue lesions not unlike the Aschoff nodules in acute rheumatic fever and when the lymphocytic infiltration was increased it caused disintegration and destruction of muscle fibers. The hearts of these animals showed enlargement.

Farranti²⁵ found in the hearts of thyroid-fed cats and rabbits swollen muscle fibers with few nuclei and no transverse striations. Iscovesco²⁶ found that repeated injections of thyroid extract produced, in rabbits, hypertrophy of the heart. Other organs such as suprarenals, ovaries, uterus, spleen and kidneys shared in this enlargement. Hoskins,²⁷ Herring,²⁸ Hewitt²⁹ and others³⁰ obtained similar results, namely: hypertrophy of the heart and hypertrophy of the other organs. Experiments by Simonds and Brandes³¹ who fed desiccated thyroid to dogs resulted in further proof that there is a thyroid hypertrophy of the heart.

Certainly the experimental feeding of thyroid can be proved.

Does the heart have more susceptibility to injury by toxic substances?

Sane³³ report an increased minute volume output of the heart in thyrotoxicosis and this increase is proportional to the increase in metabolism. The systolic output per beat of the heart decreases after thyroidectomy. Fullerton and Harrop³⁴ found a parallelism between the increase in basal metabolism and cardiac output per minute. Rabinowitch and Bazin³⁵ are the only ones who did not find an increased cardiac output in thyrotoxicosis. Robinson³⁶ studied a case of thyrotoxicosis and found that the cardiac output was actually increased to a greater degree than the oxygen consumption of the body. This means that, in this disease, there is a constant extra load imposed on the heart. In this particular case, Robinson found after thyroidectomy that the minute output fell from 10,000 cc to 3,890 cc, while the metabolism fell from plus 58 to plus one. This gives us some idea as to the great amount of work the heart does in thyrotoxicosis. Burwell and his coworkers³⁷ found a definite increase in cardiac output in thyrotoxicosis.

What are the subjective symptoms referable to the cardiovascular system in thyrotoxicosis? At the outset, let me state that there is little difference in the cardiac disturbances, between exophthalmic goiter and the adenoma with secondary hyperthyroidism. It must be remembered, however, that exophthalmic goiter is usually found in much younger individuals than is adenoma with hyperthyroidism. For that reason, we must expect physiologic changes in the cardiovascular tree in these older patients

with adenoma and secondary hyperthyroidism.

Probably the first symptom of which these patients complain is palpitation or being conscious of their heart action, usually brought on by mental or physical exertion of a mild nature. The sensation of pounding in the chest will naturally unnerve an already highly-nervous patient. Sometimes, there are attacks of palpitation of a paroxysmal nature and it is then that we suspect an irregularity. Soon these patients notice undue breathlessness or fatigue on the least exertion. It is not long, thereafter, that this dyspnea becomes more marked. The patient flushes freely and spasmodically on account of the great lability of the vasomotor system. A common complaint is the throbbing in the neck and a sense of tightness or constriction of it. Quite often distress over the precordia or a fullness in the chest may send the patient hurriedly to the doctor. This distress or fullness, even called pain by some, is not severe. There is no radiation of this discomfort and usually it is designated as being in the region of the apex or toward the anterior axillary line.

Upon *inspection*, we see increased carotid pulsation and flushing of the face and neck. The skin of the face, neck and upper chest has a salmon hue, hyperemic and somewhat pigmented. The peripheral vessels, too, may show increased pulsation. Capillary pulsations are frequently noted. Looking at the precordia, we note a forceful apex impulse which gradually increases its power and, as time goes on, the apex beat becomes diffuse and can be noted moving downward and outward.

Goodpasture²² had two cases with auricular fibrillation who died of myocardial exhaustion. One showed a focal necrosis of the myocardium and the other an extensive necrosis. However, these two patients had pathology other than the hyperthyroidism which could account for the myocardial necrosis.

More recently, Thomas²³ reports a case of exophthalmic goiter with cardiac decompensation, who died on the third day. He found a slight increase in connective tissue about a few blood vessels, a slight infiltration of polynuclears and mononuclears between the strands of fibers. The cause of death of the patient, however, was a coronary thrombus. Hashimoto²⁴ examined two hearts from exophthalmic patients and found "lymphocytic infiltration between muscle fibers or around blood vessels".

These reported cases are too few to permit us to form a definite opinion.

Goodpasture²⁵ fed rabbits thyroid extract and thyroxin and found "slight but definite lesions in the myocardium, notably perivascular necrosis or fibrosis in the wall of the right ventricle, focal necrosis or fibrosis in the papillary muscles of the left ventricle and more rarely scattered small focal necrosis within the myocardium elsewhere". "With chloroform inhalation, these animals showed widespread myocardial necrosis." He, therefore, came

to the conclusion that "hearts overstimulated by disease of the thyroid and laboring in a condition bordering on exhaustion were in a state of greater susceptibility to injury by toxic substances, such as may have resulted from a relatively mild terminal infection which, under other circumstances, might not have injured the myocardium". This conclusion is certainly well-worth remembering. Tonsillectomy or pulling of the teeth, in such a patient, may bring disastrous results.

Hashimoto²⁴ produced experimental myocarditis in animals with toxic doses of dried thyroid substances and found interstitial tissue lesions not unlike the Aschoff nodules in acute rheumatic fever and when the lymphocytic infiltration was increased it caused disintegration and destruction of muscle fibers. Iscovesco²⁷ found that repeated injections of thyroid extract produced, in rabbits, hypertrophy of the heart. Other organs, such as suprarenals, ovaries, uterus, spleen and kidneys shared in this enlargement. Hoskins,²⁸ Herring,²⁹ Hewitt³⁰ and others³¹ obtained similar results, namely hypertrophy of the heart and hypertrophy of the other organs. Experiments by Simonds and Brandes³² who fed dessicated thyroid to dogs resulted in further proof that there is an actual hypertrophy of the heart.

Certainly these experimental findings cannot be ignored.

Does the heart have more work in thyrotoxicosis? Davies, Meakins and

Sane³³ report an increased minute volume output of the heart in thyrotoxicosis and this increase is proportional to the increase in metabolism. The systolic output per beat of the heart decreases after thyroidectomy. Fullerton and Harrop³⁴ found a parallelism between the increase in basal metabolism and cardiac output per minute. Rabinowitch and Bazin³⁵ are the only ones who did not find an increased cardiac output in thyrotoxicosis. Robinson³⁶ studied a case of thyrotoxicosis and found that the cardiac output was actually increased to a greater degree than the oxygen consumption of the body. This means that, in this disease, there is a constant extra load imposed on the heart. In this particular case, Robinson found after thyroidectomy that the minute output fell from 10,000 cc to 3,890 cc, while the metabolism fell from plus 58 to plus one. This gives us some idea as to the great amount of work the heart does in thyrotoxicosis. Burwell and his coworkers³⁷ found a definite increase in cardiac output in thyrotoxicosis.

What are the subjective symptoms referable to the cardiovascular system in thyrotoxicosis? At the outset, let me state that there is little difference in the cardiac disturbances, between exophthalmic goiter and the adenoma with secondary hyperthyroidism. It must be remembered, however, that exophthalmic goiter is usually found in much younger individuals than is adenoma with hyperthyroidism. For that reason, we must expect physiologic changes in the cardiovascular tree in these older patients

with adenoma and secondary hyperthyroidism.

Probably the first symptom of which these patients complain is palpitation or being conscious of their heart action, usually brought on by mental or physical exertion of a mild nature. The sensation of pounding in the chest will naturally unnerve an already highly-nervous patient. Sometimes, there are attacks of palpitation of a paroxysmal nature and it is then that we suspect an irregularity. Soon these patients notice undue breathlessness or fatigue on the least exertion. It is not long, thereafter, that this dyspnea becomes more marked. The patient flushes freely and spasmodically on account of the great lability of the vasomotor system. A common complaint is the throbbing in the neck and a sense of tightness or constriction of it. Quite often distress over the precordia or a fullness in the chest may send the patient hurriedly to the doctor. This distress or fullness, even called pain by some, is not severe. There is no radiation of this discomfort and usually it is designated as being in the region of the apex or toward the anterior axillary line.

Upon *inspection*, we see increased carotid pulsation and flushing of the face and neck. The skin of the face, neck and upper chest has a salmon hue, hyperemic and somewhat pigmented. The peripheral vessels, too, may show increased pulsation. Capillary pulsations are frequently noted. Looking at the precordia, we note a forceful apex impulse which gradually increases its power and, as time goes on, the apex beat becomes diffuse and can be noted moving downward and outward.

Palpation reveals a rapid pulse, soft and, at times, dicrotic, it might even be somewhat of a water-hammer pulse. Tachycardia is always present. The rate varies tremendously from day to day. Elliot³⁸ tersely puts it "A patient showing a persistent tachycardia, temporary or permanent, should always be thought of at least, as a possible thyroid." Too, Gmelin³⁹ called attention to certain characteristics of the tachycardia, that it is constant with bed rest at night; that it is not influenced by drugs or narcotics, and that it disappears promptly after operation.

This increased rate is not evidence of heart disease but is evidence of a response to the increased demands made upon the heart by the increased metabolism. The precordia reveals to palpation, a forceful apex beat, first localized and then diffuse and moving to the left and downward as the disease progresses. Quite often we are led to believe that we are feeling a systolic or even a presystolic thrill. At the pulmonic area, we may feel a distinct shock due to the violent closure of the pulmonic valve.

When the heart is *percussed*, we get a definite increase of the relative dullness downward and outward; later, the right border-dullness is increased. Ofttimes the base shows an increased dullness.

Auscultation reveals a whistling sound, a bruit over the carotids and their branches particularly over the thyroid arteries. A so-called "pistol-shot" may be heard over the brachials and femorals. The sounds of the heart are loud, especially so is the first sound. Often two types of murmurs

are heard, both are systolic in time and blowing in quality. One is best heard at the third left intercostal space and is localized. The second is best heard at the apex and has a variable transmission. It is thought that the first is probably due to changes in the blood-flow, while the apical murmur is probably due to functional regurgitation at the mitral valve due to dilatation of the left ventricle. Improvement or cure of the hyperthyroidism results in the disappearance of these. It must be remembered that in hyperthyroidism, we never hear diastolic murmurs unless there is an associated heart lesion and this, of course, might be present.

Willius and Boothby, in a series of toxic thyroid patients found, for exophthalmic goiter, a blood pressure average of 147 systolic and 73 diastolic and a pulse rate of 123, while in the adenoma with secondary hyperthyroidism, the systolic average was 153 and the diastolic was 83 and the pulse rate 110. It is seen that in the toxic adenoma patient, the systolic blood pressure is elevated considerably more than it is in exophthalmic goiter and it differs also from exophthalmic goiter in that the diastolic is also increased. "It is rare to find in exophthalmic goiter a diastolic over 90, while in toxic adenomas, it is not unusual to find readings over 100." Bed rest and activity, either physical or mental, will obviously influence blood pressure readings.

Harris⁴⁰ noted a relationship between pulse rate and pulse pressure in exophthalmic goiter. In tachycardia due to bacterial toxins, acting on the heart muscle; in the tachycardia of

other forms of myocardial disease, in the tachycardia of cardiac neurasthenia and in the tachycardia of heart failure, the pulse pressure is usually diminished and Harris believes that it is only in exophthalmic goiter that there is both an increase in pulse rate and, at the same time, a high pulse pressure. It is interesting to note that blood pressure readings in auricular fibrillation are the same as in normal rhythmic cardiac action.

It is an old fact now that in thyrotoxicosis, there is an increased basal metabolism. The resulting rapid pulse rate and heightened pulse pressure is a physiologic response to bring about an increased rate of circulation. Means and Aub⁴¹ noted a close parallelism between pulse rate and metabolism in about sixty per cent of cases, while in the remainder, there was only a certain amount of parallelism. They concluded that, in exophthalmic goiter patients, just as Benedict and Murchauser⁴² concluded in normal cases, there is a relationship between heart rate and metabolism in different individuals, but in a single individual, the resting rate is a good index of the patient's progress. Sturgis and Tompkins⁴³ feel that a pulse rate at complete rest below 90 is seldom and that one below 80 is rarely associated with an increase in metabolism. This, of course, is of practical importance.

Boothby and Willius⁴⁴ in basal metabolism tests on patients suffering with primary cardiac disease, find that the level is slightly elevated in comparison to that of the normal but that in decompensated cases, there is a definite increase in the metabolism. They feel this is due to actual increase in muscu-

lar work required in labored respirations and also due to the subjective sensation of distress with resultant nervousness. DuBois⁴⁵ and Lev and Hamburger⁴⁶ report similar findings of increased metabolism in patients, suffering from primary heart disease and decompensation.

Germain Sée,⁴⁷ in 1878, emphasized the fact that the association of irregularity of the heart with exophthalmic goiter had frequently been overlooked. This is probably what we today call auricular fibrillation. Bamberger⁴⁸ as late as 1919 collected only twenty-two cases of paroxysmal tachycardia in the literature. He mentions that irregularity of the heart was present and this, of course, would suggest paroxysmal auricular fibrillation. In 1918, Krumbhaar⁴⁹ reported fifty-one cases of toxic goiter studied with the electrocardiograph. He found four cases with sinus arrhythmia, three with ventricular extra-systoles, three with auricular fibrillation, one with auricular flutter and two with delayed conductivity. In 1922, Hamilton⁵⁰ found eighteen cases of auricular fibrillation in 200 cases of hyperthyroidism. He says that "very few cases of hyperthyroidism over fifty fail to show auricular fibrillation." Willius, Boothby and Wilson^{13, 14} in 377 patients with thyrotoxicosis found constant auricular fibrillation in eight per cent and transient auricular fibrillation in nine per cent of the exophthalmic goiters, while in toxic adenomas, they found ten per cent in each group. They emphasized that the *duration* of the increased metabolic rate is most important in regard to development of auricular fibrillation. Phillips and Ander-

son⁵¹ conclude that auricular fibrillation is the most common cardiac irregularity associated with hyperthyroidism and that it will usually disappear, if thyroidectomy is performed before the heart has been permanently injured. It is interesting to note that Stewart and Crawford⁵² found experimentally on dogs that the heart is less efficient in the propulsion of blood, during irregular tachycardia than during the normal slower rhythm.

Willius, Boothby and Wilson found fifteen per cent of cases to have extrasystoles, which they feel have no significance in thyroid disorder. Paroxysmal tachycardia was not a common disorder in thyroid disease, occurring in about one per cent of cases.

Hoffman,⁵³ in 1914, was the first to describe high T-waves in the electrocardiograph tracings of patients, suffering with exophthalmic goiter. Krumbhaar⁴⁰ described an "unusually prominent T-wave in most cases of toxic goiter which, in about one-half of the cases, was markedly and persistently diminished after operation." Furthermore, he states that a diphasic or inverted T-wave, especially in Leads I and II, offers an unfavorable prognosis. Willius, Boothby and Wilson do not comment on the height of the T-wave except to call attention to the infrequency (one per cent) of inversion of the T-wave. This infrequency is due to the fact that degenerative changes in the myocardium are not common in hyperthyroidism. Hamburger⁵⁴ and his co-workers report several cases of their series as having a high T-wave which showed a definite lowering of the height when the thyroid was removed. Previous rest with-

out iodine has no effect but with iodine a lowering of the T-wave in most cases is noted. They, however, found no uniformity in the increased height and concluded that it had little, if any, relation to pulse rate. It is well to remember in this connection that Rothberger and Winterberg⁵⁵ found in patients, having a marked accelerator tone, a high T-wave.

The association of hyperthyroidism and angina pectoris is rare. Lev and Hamburger⁵⁶ report six cases; Sturgis⁵⁸ reports one case. Hurxthal¹⁵ found two cases with angina pectoris out of 500 cases of cardiac failure with hyperthyroidism. Haines and Kepler⁵⁷ remark that it is easy to overlook angina pectoris in the presence of severe hyperthyroidism, or mild hyperthyroidism in a patient with angina pectoris. A heart having a coronary supply which is sufficient under ordinary circumstances, may be inadequate to meet the demands placed upon it by the added work of the heart produced by hyperthyroidism and hence, the patient suffers pain. An interesting case, which recently came to my attention, was that of a patient with myxedema of, at least, ten years standing, with a minus metabolism of forty-three, who had a bundle-branch block and who suffered definite attacks of angina pectoris when she received over one and one-half grams of thyroid extract.

Sturgis⁵⁸ reports a similar case of myxedema with associated heart disease in whom attacks of angina pectoris were produced when more than one-half gram of thyroid extract was taken.

Recently, we have read many articles regarding cases of so-called "masked hyperthyroidism." It was Charcot,⁵⁹ in 1885, under the heading "Maladie de Basedow formes frustes," who called attention to a group of cases in which one of the triad of characteristic symptoms of exophthalmic goiter was missing. Chvostek,⁶⁰ in 1887, considered these formes-frustes cases as "symptom poor" cases in contrast to the well-developed typical cases. Levine and Sturgis,⁶¹ in 1924, under the title "Hyperthyroidism Masked as Heart Disease," reported five cases. Priest⁶², in 1926, reported three cases of hyperthyroidism, simulating primary heart disease. In 1928, Tucker⁶³ reported three cases of hyperthyroidism without visible or palpable goiter. Hamburger and Lev⁶⁴ report five cases, under the title of "Masked Hyperthyroidism." Freund and Cooksey⁶⁵ also report five cases of thyrotoxicosis, without visible or palpable thyroid. These patients are middle-aged individuals, who do not present the classical picture of hyperthyroidism, but who show a group of symptoms which, if analyzed, will place them in the hyperthyroid field. They have a staring expression of the eyes, an increased warmth, redness or pigmentation of the skin, increased restlessness and unexplained loss of weight, and come to the doctor with a complaint in one of the main systems, quite often cardiovascular. They have a persistent increased metabolism and under iodine medication or thyroidectomy, they improve or get completely well. This group must be kept in mind, as its ranks are increasing due to the added stress and strain

which men and women over forty-five are now experiencing.

All of us have seen cases of hyperthyroidism which give no history of previous heart involvement and still have symptoms of heart failure. Hurxthal¹⁶ studied 500 cases and came to the conclusion that the average age of congestive heart failure was above forty with a large percentage showing previous cardiovascular disease. He feels that "thyrotoxicosis has a specific excitatory effect on the heart and that this, more than the demands for increased work, produces failure in a heart weakened by the degenerative processes of age." In his opinion, the most significant causes of congestive heart failure in hyperthyroidism are age and its accompanying cardiovascular changes, the specific heart drive, auricular fibrillation, and the duration and intensity of thyroid activity. Andrus⁶⁶ feels that when congestive heart failure appears under forty that there must be "a pre-existent rheumatic or more rarely a syphilitic heart disease." If you will review your own cases, you will be struck by the fact that the majority of these congestive heart-failure patients were older individuals, who, for many years, had adenomatous thyroids with secondary hyperthyroidism. These patients usually give a history of many exacerbations and remissions.

A review of this kind would certainly lack completeness, if I did not discuss a condition more prevalent than even thyrotoxicosis. I mean the syndrome of neuro-circulatory asthenia or "effort syndrome" as it affects the cardiovascular tree and which might even be mistaken for a toxic thyroid

heart You can well imagine the difficulty in diagnosis when such a patient has an associated enlarged thyroid.

Addis and Kerr⁶⁷ examined many recruits, during the war, and found these embryonic soldiers were complaining of increased pulse rate, tremor, and of cold, moist hands which became cyanosed when dependent. They even complained of precordial pain with dyspnea and palpitation on moderate exertion, dizziness, flushing and fainting. This condition was found both in patients who had normal-sized thyroids and those who had enlarged thyroids. Addis and Kerr felt that the thyroid had no etiologic relationship to the nervous picture. Plummer, though, feels that these patients with neurocirculatory asthenia are more prone to thyroid enlargement than are normal individuals.

Remember, in this condition, that this tachycardia disappears with rest and sleep. Dell'Acque and Aschner⁶⁸ noted in hyperthyroidism that the average pulse rate increased 4.82 upon changing from a reclining to a standing posture, while in neurotic patients, it was five times as great, namely, 25.3. This might be a good diagnostic point. Peabody and his co-workers⁶⁹ found that the basal metabolism was normal

in soldiers with so-called "irritable" hearts and furthermore they were impressed with the fact that these patients showed a marked tachycardia, easily provoked by mental or physical strain, which disappeared when they were allowed to lie down for a short period.

SUMMARY

Parry should be given credit for first describing thyrotoxicosis and especially so its cardiac manifestations. The fact that cardiac complications, in young people, are infrequent; the fact that severe intoxications give no clinical picture of decompensation in previously undamaged hearts, the fact that after complete relief, by thyroidectomy in previously undamaged hearts, there is a complete return of normal cardiac findings, all tend to uphold the opinion that hyperthyroidism does not cause permanent myocardial changes. As the so-called "irritable heart" in neurocirculatory asthenia approaches in symptomatology the heart in thyrotoxicosis, we must not lose sight of the variations in tone of the vagus and sympathetic nerves, which might play a cardinal rôle. In a practical consideration of this topic, it is well ever to keep in mind that hyperthyroidism does cause marked subjective heart symptoms.

Editorials

THE PROGRAM FOR THE GENERAL SESSIONS OF THE SIXTEENTH ANNUAL CLINICAL SESSION IN SAN FRANCISCO

In the week of April 4, 1932, will occur one of the great medical meetings of the year. The Annual Session of the College has become a focal point for those interested in the medical, as contrasted with the surgical, interests of our profession.

That the College is meeting a need in medicine on this continent has been attested by its remarkable growth in numbers and in influence during its relatively short existence, and particularly during the period of less than a decade following its reorganization. The College stands today as representative of those practitioners who are concerned with both the science and the art in medicine, as the American College of Surgeons is a meeting ground for those concerned with the surgical specialties. The College has not attempted, nor has it manifested at any time a desire, to invade the fields so well cultivated by the American Medical Association, The American Hospital Association, The Association of Medical Colleges and other associations formed for promotion of their own various interests. The primary purposes of the College are the encouragement and preservation of high standards, the dissemination of knowledge within its field and the elevation of the historic and esthetic ground in which medicine, as

one of the learned professions, grows. There is no desire to set the members of the College apart from other medical men; but there is clearly shown a desire to stimulate all men in medicine to the level of professional, ethical and cultural achievement at which fellowship in the College is possible.

Each session of the College has reflected the purposes and ideals thus briefly stated. The San Francisco Session will be the first to be held beyond the Mississippi. While the United States census has shown in recent decades only a slow movement of the center of population westward along the thirty-ninth parallel, located now in southwestern Indiana, there has been a remarkable development, not only in population, but also in power, in influence and in culture along the entire Pacific Coast. Here a people from the same ethnic sources and with, in general, the same cultural and political purposes as found in our population eastward has accumulated. But this people has a genius of its own. There is a freshness in its point of view, an exuberance in its spirit, and a capacity for building great industries and noble institutions that set it somewhat apart, due, no doubt, in good measure to its sea and valley and mountain. San Francisco occupies a position near the center of the great

empire and this makes it a fitting seat for the first meeting of the College to be held within its bounds

Two great medical schools form the nucleus of an important medical center. The medical school of the University of California, with the Hooper Foundation for Medical Research, and the Stanford University Medical School are known the world over. These institutions, with their laboratories and hospitals, together with all other medical facilities around and about the Bay of San Francisco, have been placed at the disposal of the College for the week of the meeting. Each morning, on Tuesday, Wednesday, Thursday and Friday, clinics and demonstrations will be held in which the advanced work in these institutions will be exemplified. As is customary, each member of the College will be given an opportunity, long in advance of the meeting, to choose the places he desires to visit and the men and subjects he wishes to hear. This is arranged from the office of the Executive Secretary of the College and the early disposal of this matter, which might otherwise be confusing, lends order to this part of the program. The arrangement of the laboratory and clinical portion of the program is in the hands of Dr. Wm. J. Kerr, Professor of Medicine in the University of California, who is general chairman for the Session. This will be the second meeting in which the President of the College has been responsible for the program of the general sessions, attended by all fellows, associates and guests, and in which all the formal papers and addresses are presented. There will be five after-

noon and two evening sessions of this character. On Monday the short introductory program of welcome will be followed by scientific papers. On Monday evening a program of extraordinary interest will be presented. On both Tuesday afternoon and evening the scientific sessions will continue, while on Wednesday, Thursday and Friday, only the afternoons will be thus occupied, Wednesday and Thursday evenings being given over to the convocation and the banquet.

For the seven afternoon and evening sessions set aside for the presentation of scientific and practical matters before the entire group, a program of outstanding merit with some unique features is being arranged. This seemed to your President to be an opportunity for the exposition of the best medicine on the Pacific Coast. Men deemed capable of sound and scientific presentation have been invited to take part and their response has been very gratifying. The members of the College will thus have an opportunity to see and hear a remarkable group not so commonly seen and heard when the programs are given farther east. This opportunity of contact with men about whose work we know and yet with whom contact has not been as frequent as desired will be a feature of great value and interest.

While there is an unusual number of new names on our program, both from the coast states and from the country at large, the outstanding names in medicine will be well represented. This is not the time nor place to detail names and subjects but it may be said that a program of wide

range and interest has been arranged. Final selection of many offerings is still to be made. Experience has shown that not more than about fifty papers and addresses can be well presented in the allotted time, giving fifteen to twenty minutes to each presentation, with an occasional extension of time when the interest of the subject requires it.

Even to suggest the wide range of subjects offered would be difficult, but the appearance of certain trends in modern medicine makes this attempt worth while. There will be the study of the physics and physiology of arteriosclerosis and hypertension by a master. Pulmonary arteriosclerosis and the congenitally narrowed aorta have a place. The onset of decompensation of the heart in elderly patients, a follow-up study of hypertension, and an experimental and clinical study of the effect of hypothyroidism upon the heart with two studies of an extensive material, one on cardiovascular syphilis and one on the electrocardiograms, will give valuable contributions to our knowledge of the heart and blood vessels. The lungs and bronchi are studied from several angles. Atelectasis and tuberculosis, the treatment of cavities, some observations on pulmonary emphysema and the rôle of bacteria in asthma will be among the subjects of unusual interest. The liver will receive attention with subjects ranging from the effect of the administration of glucose and insulin on the glycogen content, to an unusual study of tumor carcinoma of the liver in the light of its relation to the kidneys, and a study of cancer and of its relation to the endocrine system. High-

disease and a study of the relationship of nephritis and nephrosis.

The practical applications of recent discoveries in the field of gastro-intestinal physiology, the absorption of sugar from the intestinal tract, the clinical aspects of gastric secretions, and the elements of error in diagnosis in jaundiced patients are to be discussed. On the subject of the adrenal glands, there will be presentations of unusual significance from both the experimental and clinical standpoints. The biological and clinical importance of ovary-stimulating substances will be brought out. There will be a study of calcium metabolism and diseases of the parathyroid gland. Recent studies on the chemical pathology of epilepsy and on its treatment appear. We will learn something more of the mechanism of edema formation in disease. There is a study of leukopenia, on the action of benzol, roentgen rays and radium on the blood and blood-forming organs, on the relation of paranasal sinus infection to disease elsewhere, on the clinical significance of the atrophic tongue; and on the experimental basis for vaccine treatment of chronic arthritis with a summary of results of treatment. There will be studies on the chemotherapy of amebiasis, together with a consideration of human amebiasis.

While there will be many groupings of papers on allied subjects, symposia do not constitute an outstanding feature of the program. One symposium, however, will make up for the lack of many others. Recent years have seen an almost unbelievable advance in our knowledge of the involuntary nervous system. Not only have the anatomist

been able to construct a fairly comprehensible picture of it but the physiologists have delved deeply into its function in many species of animals and very recently have added greatly to our knowledge of hormonal control. Pituitary hormone, adrenalin and acetyl cholin have been subjected to such intensive study that their actions are becoming quite thoroughly known. Much has been learned recently of the sympathetic control of the kidneys and of blood pressure, of the peripheral vessels, of the gastrointestinal tract and of the urinary bladder. Even as this knowledge has been developing, surgery has been making use of it. It, therefore, seems that a symposium on the involuntary nervous system, which would bring together the anatomist, the physiologist, clinicians in medicine, and surgeons, would be of the most profound interest. If you think of the names of the men you would most wish to hear on these subjects, you will be likely to find them on the program when it is finally announced. An outstanding anatomist in this field, and the two greatest physiologists in this country, are on the program for this symposium.

The history of medicine has been given a place on previous programs, notably that of the Minneapolis meeting, and approval of this feature by the Fellows has been very general. At this time of unrest and uncertainty, affecting medicine as it does all other walks of life, an address on medicine in Utopia will be particularly appropriate. Many books on Utopia have been written and the relation of the ideas about medicine in that happy land

will have an immediate interest. There is a lively story on medicine on the Pacific Coast and it is hoped that this can be made available.

Many other items of interest are on the program but this will suffice to show that the program of the General Session of the San Francisco meeting promises to reach the high standards set in recent years. The opportunity of securing low rates of travel to the coast, the extension of time customary for travelers to this region, the opportunity either preceding or following the meeting for vacations in the land of sunshine and flowers, should make the San Francisco Session one of the most attractive we have ever held. Subsequent issues of the *ANNALS* will give all the details of arrangement and of the program. It is to be hoped that all Fellows will give a ready response to the efforts of our California hosts.

THE SASKATCHEWAN EXPERIMENT

In Saskatchewan, and to a less extent in Manitoba, there is in operation a "municipal doctor" system which is intended to solve the problem of obtaining good medical care for the residents of certain rural communities. The character of this system with its policies and procedures is the subject of the eleventh publication of the Committee on the Cost of Medical Care, by C. Rufus Rorem. The rural municipality, composed of nine townships, is entirely apart as a unit of government from such cities, towns or villages as may be situated within its area. Each

rural municipality is a unit for administrative purposes, including the levying of taxes. In Manitoba there are three, and in Saskatchewan there are twenty municipalities which employ full-time physicians and levy taxes to pay for this service. Twelve others make grants of \$1,500 or less as inducements to physicians to practice in their communities, and as remuneration for services as public health officers and for the care of indigent persons. The median salary of the twenty full-time municipal doctors in Saskatchewan is \$4,000. Each serves an average population of about 1,800, receives from 1,000 to 1,500 office calls annually, and makes from 300 to 500 visits to the homes of patients. Notwithstanding the full-time status, opportunity is provided in nearly all cases for the municipal physician to earn additional income from special services. In some instances he is directed to make nominal charges for specified services. An interesting example of these is a fee for the "initial" house visit in any illness. Apparently the object of this is to discourage house calls for minor conditions which could be properly treated at the office. Most of the municipalities levy taxes upon the basis of the value of farm lands and the municipal physician levy usually amounts to between \$7.50 and \$10.00 per family. Arrangement is usually made by which transients and residents not eligible to the service may be treated upon a fee basis. The doctors themselves say that while they do more work they also receive a larger net income than could be earned by private practice in the same areas, partly because there are no "bad debts." Certain advan-

tages and disadvantages of this entire system, which is fundamentally merely contract practice, are obvious. Opposition has come largely from non-resident landowners, from well-to-do farmers with small families, and from those living close to the doctor's office. Independent physicians in towns included within the areas of the rural municipalities using this system and in adjacent communities recognize that the presence of municipal physicians has had unfavorable economic effects upon their practice; and private physicians in Saskatchewan on the whole express disapproval of the system, although they admit that in certain rural areas it may be the only way to assure the continued presence of a medical practitioner. This, as well as other modifications of the time-honored relationship between physician and patient in private practice, should receive careful attention and study. Whether his initial reaction is one of strong disapproval or not, the medical man of today can ill afford to be indifferent to such tentative schemes for altering medical economics. Rather should he study and weigh each of them that he may be prepared to exercise a constructive directing influence if occasion arises. If modifications are ever found necessary, they should originate within the medical profession itself, and not be foisted upon it. They should represent the best constructive thought of which the medical mind is capable. Only through such active participation in the economics of public health can the medical profession hope to uphold those high standards of practice which are absolutely essential.

ACCIDENTAL INJURIES AND OCCUPATIONAL DISEASES

In a recent decision, the Tennessee Supreme Court (*Morrison vs Tennessee Consolidated Coal Co*, 39 S W (2nd) 272, decided June 10, 1931) holds that there is no recourse under the workmen's compensation act for a disease, occupational or otherwise, unless that disease naturally results from an accidental injury. Further "an injury to be regarded as an accidental injury under the compensation act, must be an injury unforeseen, unexpected, and fortuitous. An element of unexpected casualty must be present." Likewise, the origin or inception of the disease must be assignable to a determinate or single occurrence identified in space or time, it was pointed out. This decision is seemingly in accord with the general usage of the terms in the statutes and probably rightly interprets the spirit of the earlier phase of the movement to insure compensation for occupational injuries. However, it should attract attention to the fact that there is a general tendency to apply the principle of compensation more broadly than the original intent of the law. In addition to those occupational in-

juries which are accidental in the sense defined in the decision to which reference has been made, many now consider it both proper and desirable that compensation should be paid for those injuries which grow out of the long continued operation of the causes of occupational disease. Here the situation is somewhat different. In many instances, instead of the element of the unforeseen, unexpected and fortuitous casualty being present, the worker has entered upon his employment in full knowledge that a hazard existed and has elected, although it may be under the stress of necessity, to expose himself to that hazard. One must feel in accord with the desire to give such workers compensation, especially when they have not been made aware of the hazards existing. It would seem, however, that cooperative insurance with the cost apportioned between the employer and the employed more justly meets the needs of this group. At least, it is highly desirable that statutes providing compensation for occupational injuries and occupational diseases be so framed as to discriminate between the various classes of those entitled to the benefits which are provided.

Abstracts

The Etiology of Gall Stones I Chemical Factors By RUDOLPH SCHOENHEIMER and LEO HRDINA (Proc Soc Exp Biol and Med, 1931, xxviii, 944-945)

The problem of gall stone formation is the problem of the precipitation of cholesterol out of the bile. The question has been investigated as to whether the ability of bile to hold cholesterol in solution might be due to some one or all of the bile acids. It was found that the precipitation of bile acids from human bile by ferric chloride, by lead acetate, or by any other means produces a simultaneous precipitation of cholesterol. The complexes of bile acids and cholesterol are readily soluble in water and may be purified without lessening the cholesterol content. Large amounts of these complexes have been isolated from human bile in which it appears that all or nearly all of the cholesterol is thus bound. In dog or ox bile, on the contrary, most of the bile acids are in combination with fatty acids rather than cholesterol. This explains the complete absence of cholesterol-containing gall stones in these animals. As for man, this investigation shows that whenever the organism by any pathological processes brings about a significant lowering of the bile acids in the gall bladder in relation to the amount of cholesterol in it precipitation of cholesterol is bound to occur.

The Etiology of Gall Stones II Rôle of the Gall Bladder By EDMUND ANDREWS, RUDOLPH SCHOENHEIMER and LEO HRDINA (Proc Soc Exp Biol and Med, 1931, xxviii, 945-946)

Under normal conditions the gall bladder concentrates bile in its concentrating effect upon the bile salts, while it absorbs water rapidly; while bile salts and cholesterol if they are absorbed at all, are absorbed at an equal rate. In the case of gall stones there is no longer that concentration of bile salts to hold

the cholesterol in solution. In a series of experiments in which the cystic duct was ligated, leading to infection of the gall bladder, with added traumatic insult, the action was diametrically opposite in respect to differential absorption. In every case an increase in the concentration of cholesterol was found, averaging + 29 per cent, and a lessening in the concentration of the bile salts, averaging - 28 per cent, was found. The ratio of bile salts over cholesterol was 97 for normals and 59 for sixteen experiments. This change is sufficiently marked to cause precipitation of cholesterol if continued for any length of time. Apparently the gall bladder mucosa has great absorptive power for bile salts if diseased.

The Etiology of Gall Stones III Bile Salt-Cholesterol Ratio in Human Gall Stone Cases By EDMUND ANDREWS, RUDOLPH SCHOENHEIMER and LEO HRDINA (Proc Soc Exp Biol and Med, 1931, xxviii, 947-948)

The two preceding studies having suggested that cholesterol stones are found in the human gall bladder because there are not enough bile salts present to hold the cholesterol in solution, one would expect to find in human gall bladders with cholesterol stones a lesser quantity of bile salts. Results of analyses confirm this expectation. In a group of operated cases the bile salt-cholesterol ratio was found to average 3.4, and in the mixed bladder bile from 30 examples of cholelithiasis found post-mortem this ratio was 0.6. The control series of Newman on normal human gall bladders gave a bile acid-cholesterol ratio of from 10 to 24; and Hammarsten found ratios of 10 and 30 respectively in two cases of sudden accidental death. These figures add further proof to the theory that cholesterol stones are due to a fault, differential absorption of bile acid and cholesterol by the abnormal gall bladder mucosa.

Lead Poisoning in Brass and Bronze Foundries By FRANK G. PRIDLEY, M.D., D.P.H. (The Canadian Med Assoc Jr, 1931, xxv, 299-303)

Lead poisoning is an important hazard in certain types of bronze foundries. Bronze is essentially an alloy of copper and tin, and brass an alloy of copper and zinc. However, this distinction is not always observed in naming alloys. Lead is frequently added to both, sometimes to improve them, sometimes to cheapen them. In railroad bronzes, such as bearings, the antifrictional qualities of lead make it a valuable constituent and it may be present in amounts as high as 20 per cent. The hazard arises in part through the volatilization of lead at the temperature necessary to insure the melting of the copper constituent in the preparation of the alloy and during the subsequent pouring of the molten alloy, and, in part, from the subsequent grinding and polishing of the castings. Of 38 men engaged in the founding of high lead bronze, 24 were found to be suffering from acute lead poisoning, nine others showed definite evidence of lead absorption, and only five showed no evidence of plumbism. Three brass polishers who succeeded each other on the same emery wheel became poisoned with lead. Blood smears were examined from 26 men engaged in polishing low lead brass and bronze (less than six per cent lead). Five of these showed stippled cells in a number well in excess of 200 per million red cells. It is the belief of the author that lead plays an important part in the disease pictures variously diagnosed as brass poisoning, bronze poisoning, and copper poisoning.

The Relation of Heredity to the Occurrence of Spontaneous Leukemia, Pseudoleukemia, Lymphosarcoma and Allied Diseases in Mice, Preliminary Report By MAUD SLYE (Am Jr of Cancer, 1931, xv, 1361-1385)

The familial occurrence of human leukemia and of the related lymphatic diseases has been noted repeatedly. While the data in each individual report are few, they are

all in agreement in indicating that in man the leukemic diseases have an hereditary basis and tend to run in families, and, further, that they tend to occur in cancer strains. Dr Slys found 975 examples of the leukemic diseases in the first 50,000 mice autopsied by her. The division between the sexes was practically equal. All instances of leukemia, pseudoleukemia, and lymphosarcoma were in families carrying other forms of malignancy. All occurrences of these diseases have been in a limited number of strains of mice. Whole races of mice of other derivation, but living for many generations under identical environmental conditions, have been entirely free from these conditions. The difficulty in certain recognition and differentiation of members of this group of diseases by histopathological methods is fully recognized, yet the results obtained furnish both negative and positive evidence for the assumption that the tendency to these diseases and the absence of these diseases are both subject to the control of heredity. Likewise since the leukemic diseases were found to occur in cancer strains only, there is strong evidence in support of the view that the leukemias, pseudoleukemias, and lymphosarcomas are members of the neoplastic group.

Tumor Immunity By THOMAS LUMSDEN, M.D. (The Am Jr of Cancer, 1931, vi, 563-640)

From extensive experimentation with several strains of transplantable tumors, Lumsden believes that it may be safely concluded that anti-malignant-cell bodies, lethal to cancer cells but harmless to normal tissue cells, can be produced. When an implanted tumor already established in the body is gradually destroyed by injecting antiserum or formalin into it, active immunity against the tumor is induced by a mechanism which may be called autovaccination. It has still to be learned whether similar effects can be obtained with spontaneous tumors, in which the relationship between host tissue and invading tissue may be quite different.

Reviews

The Pathology of Internal Diseases. By WILLIAM BOYD, M D, M R C P, Ed, Dipl Psych, F R S C, Professor of Pathology in the University of Manitoba, Pathologist to the Winnipeg General Hospital, Winnipeg, Canada xvi + 888 pages 298 illustrations Lea and Febiger, Philadelphia, 1931 Price, \$10.00

This is a companion volume to the author's *Surgical Pathology*, with only a minimum of unavoidable overlapping between the two. It aims to present the pathology of those diseases which are found in the medical wards of a teaching hospital and to relate their signs and symptoms to deviations from the normal in morphology and function. In this it succeeds admirably. Naturally no one pair of book covers can enclose all of the material which the subject foreshadows. Certain gaps must occur. Certain infectious diseases, diseases of special importance in the tropics, and others in regard to which no clear cut pathological picture has been established, have been intentionally excluded. In many respects the choice of material has been made with great skill. Throughout, special attention is given to presenting the newer knowledge in pathology, not that which is so new as to be ephemeral, but the very things which, although well established, the internist will find entirely wanting or very sketchily given in his older books. This is a pathology text of intriguing interest for the upper class student and the practitioner whose interest is not with the fundamental tissue lesions as such, but with the pathological processes of individual disease conditions. The reviewer finds himself very often in sympathetic accord with the point of view of the author in various matters that are not accepted by all. For instance, the fact that rheumatism in its various forms and gradations is a fairly well unified series is

clearly emphasized, so-called acute massive collapse of the lung is not considered a condition *suu generis* but merely a special manifestation of pulmonary atelectasis, and toxic adenomas of the thyroid and exophthalmic goiter are grouped under the heading of Graves' disease. However, it is not because of general agreement with its subject matter that the writer commends this work. It is rather because he realizes its splendid usefulness as a text in special pathology, as collateral reading in internal medicine, and as a reference book for the practitioner who wishes to keep up with the advances in pathology.

Deep X-Ray Therapy in Malignant Diseases. A Report of an Investigation Carried Out from 1924-1929 under the Direction of the St Bartholomew's Hospital Cancer Research Committee. By WALTER M. LEVITT, M B, D M R E, Medical Officer in charge of the Radiotherapeutic Research Department. With an introduction by SIR THOMAS HORDER, Bart, K C V O, M D, F R C P, Chairman of the Cancer Research Committee. 128 pages. John Murray, London, 1930. Price, 10 s 6 d, net.

This report gives the technical methods employed and the results obtained during the several years that the St Bartholomew's Cancer Research Committee (formerly the Radiotherapeutic Research Committee) has been actively engaged in the treatment of malignant disease by irradiation. Two main types of therapeutic technic were developed: (1) intensive single-dose technic in which the entire dosage is applied in one, or at the most in two or three days, and (2) intensive split-dose technic in which the dose is applied in several fractions at intervals of approximately 24 hours over a period of several days. The

number of fractions varies from 6 to 30. In 85 cases radium was used in addition to x-rays. So different are the results obtained in carcinoma of various regions that mass statistics are without meaning, and when split up into the necessary groups, the total number of cases in each is not large enough to be impressive. However, a certain degree of encouragement is afforded. Of 43 cases of inoperable carcinoma of the breast, 6 were still living at the time of report without signs of cancer present. In three of these, three or more years had elapsed since treatment. Thirteen of 60 cases of malignant disease of the uterus, chiefly carcinoma of the cervix, were reported alive without evidence of growth present. This was true also of 27 out of 170 cases of malignancy of the upper air passages. In the portion of this group suffering from carcinoma of the tonsil, the results were uniformly poor. Twenty-six cases of malignancy of the rectum were treated in the period under review, and of these only one was without evidence of the disease. In about 29 per cent of all cases treated, x-rays failed to have even a palliative effect, and in a further 22 per cent only minor degrees of improvement were observed, or improvement was of but short duration. In view of the statistical results, the conclusions stated in this report seem somewhat too sweeping, as being true of but a limited proportion of the cases. One must remember, however, that these patients were considered inoperable, and any salvage of human life or even temporary return to a state of economic independence, is something gained.

Resistance to Infectious Diseases. An Exposition of the Biological Phenomena Underlying the Occurrence of Infection and the Recovery of the Animal Body from Infectious Disease, with a Consideration of the Principles Underlying Specific Diagnosis and Therapeutic Measures. By HANS ZINSSER, M.D., Professor of Bacteriology and Immunity, Medical School, Harvard University, formerly Professor of Bacteriology at the College

of Physicians and Surgeons, Columbia University, and Bacteriologist to the Presbyterian Hospital, New York, formerly Professor of Bacteriology and Immunity, Stanford University, California. Fourth edition, completely revised and reset. xviii + 651 pages. The MacMillan Company, New York, 1931. Price, \$7.00.

Under this new title appears the fourth edition of Zinsser's *Infection and Resistance*. Advances which have been made in the eight years since the third edition came out have produced profound modifications in the theories of immunology and consequently in their application to methods of diagnosis and therapy. Many chapters have required rewriting in order to introduce new material and to eliminate that which has been discarded. The first section of the book, 486 pages, deals with fundamental conceptions and theories, while the second section discusses the problems of immunology as applied to individual infectious diseases. While the first portion of this book is indispensable to the teacher and laboratory worker, the second section will be of interest and value to the practitioner. Here are found full discussions of immunity in syphilis and tuberculosis, and of the applied principles of immunization in scarlet fever, pneumonia, typhoid and paratyphoid fever, meningitis, rabies, plague, cholera, anthrax, influenza, small pox and various other infectious diseases. This book can be heartily recommended to those who seek a comprehensive and authoritative text on immunology. Numerous bibliographic references, arranged as footnotes, give the sources of material other than that by the author. It is unfortunate that many of these references lack the page number, a very important aid after journals have been bound.

Food Allergy. Its Manifestations, Diagnosis and Treatment with a General Discussion of Bronchial Asthma. By ALFRED H. ROWE, M.S., M.D., Lecturer in Medicine in the University of California Medical School, San Francisco, Calif., Chief of the Clinic for Allergic Diseases of the Alameda County Health Center, Oakland,

Calif., etc xi + 442 pages 1931, Lea and Febiger, Philadelphia Price, \$5.00 net

Forty-three per cent of 400 unselected individuals were found to give a family history of allergy, and a personal history of allergy occurred in thirty-five per cent of this group. In general, statistics show a probable food allergy in upward of thirty per cent of all persons. In the monograph under review the author treats this important subject in an extremely complete manner. The many diverse characteristics and manifestations of food allergy are described as they affect the gastro-intestinal system or result in bronchial asthma, eczema, urticaria or angioneurotic edema. Diseases less commonly related to allergy in diagnosis such as migraine, neuralgia, arthritis, bladder allergy, etc., are also considered. The frequency of negative skin reactions is emphasized and the method of "elimination diets" which was devised by the author is fully set forth as applied to both diagnosis and treatment. All internists will be interested in the section on the allergic aspects of drug sensitizations. This monograph is admirable in its completeness, in its scientific approach and in the reserve with which a subject has been handled, which might easily have led a specialist to make extravagant and unsupported generalizations. An extensive bibliography is provided.

Recent Advances in Cardiology By C. F. JERRELL FARR, M.A., M.D. (Oxon), F.R.C.P. (Lond.), Junior Physician, King's College Hospital, Physician, Woolwich Memorial Hospital, Sometime Radcliffe Travelling Fellow, University College, Oxford and C. W. CURTIS B.Sc., M.C., M.B. (Oxon), M.R.C.P. (Lond.); Physician Harrogate Infirmary. Second edition xi + 353 pages 10 plates and 62 text-figures. P. Blakiston's Son & Co., Inc., Philadelphia, 1931. Price, \$3.50.

This is the second edition of the Cardiology series of the *Recent Advances* series. It is a well-written and comprehensive treatise on the subject of cardiology.

Certain sections have been entirely rewritten in this edition. Much attention is given to electrocardiographic findings throughout, and one chapter is devoted entirely to this method of examination. To the reviewer the presentation of myocardial syphilis seems entirely inadequate, for only the extremely active diffuse form is considered. The final chapter on the interpretation of certain misleading physical signs and symptoms which may be encountered even in those with presumably healthy hearts is especially important in connection with routine physical examinations. For the practitioner this will prove an extremely useful manual.

Lane Lectures on Pharmacology By WALTHFR. STRAUB M.D., Ph.D. (h.c.). Professor of Pharmacology, University of Munich. (Stanford University Publications, University Series, Medical Sciences, Volume III, Number 1) 88 pages, 9 text-figures. Stanford University Press, Stanford University, California, 1931. Price, postpaid, paper \$1.00, cloth, \$1.50.

Professor Straub chose as subjects for his six Lane Lectures, delivered in San Francisco in April, 1929, the following: Intoxicating Drugs, Ways to Ideal Anesthesia, Digitalis—Chemistry, Digitalis—Biochemistry, General Pharmacology of Heavy Metals, Camphor and the Modern Analeptics. These topics are discussed in an interesting and thought-provoking, rather than an exhaustive, manner. An index is provided.

Hemorrhoids The Injection Treatment and Pruritus Ani By LAWRENCE GOLDBACH, M.D., Philadelphia. Second edition 207 pages, 31 illustrations. F. A. Davis Company, Philadelphia, 1931. Price, \$3.50 net.

This second edition of a manual on the treatment of hemorrhoids and pruritus ani by the injection method gives several changes in technique as compared to the first edition. The author's instruments and method of using 5 per cent phenolized oil are clearly set forth. Etiology, pathology and symptomatology are adequately pre-

sented and the book is well-printed and well-indexed

Rheumatic Fever—A Heart Disease By JOHN L. CHESTER, M.D., F.A.C.P., Attending Physician and Lecturer to the Training School, Providence Hospital, Detroit, Attending Physician and Chief of the Heart Service, Eloise Hospital, Eloise, Michigan 122 + 4 pages Privately printed, 1929

This is a concisely written monograph bringing together the best of recent advances in the field of rheumatic cardiac disease. It is illustrated by case reports from the cardiac service of Dr F. N. Wilson at the University of Michigan Hospital, Ann Arbor.

Lehrbuch der allgemeinen Physiologie Edited by ERNST GELLHORN, Ph.D., M.D., formerly Professor of Physiology at the University of Halle, Associate Professor of Physiology at the University of Oregon, Eugene, Oregon xiii + 741 pages, 126 illustrations. George Thieme, Leipzig, 1931. Price, in paper, M. 47, bound, M. 49.50.

In the preparation of this textbook of general physiology the editor named has had the aid of Professors Asher of Berne, von Buddenbrock of Kiel, Oppenheimer of Berlin, and Spek of Heidelberg. It treats physiology more particularly from the standpoint of recent advances in physico-chemistry. It should prove valuable to the more advanced students in the related fields of general biology, embryology and pathology, as well as to the physiologist.

Die Bakteriologie der Wurmfortsatzentzündung und der appendikulären Peritonitis By W. LOHR, Magdeburg, and L. RASSELD, viii + 96 pages, 46 illustrations and 11 tables. George Thieme, Leipzig, 1931. Price in stiff paper cover, M. 12.

This well-arranged monograph deals with the bacterial content of the healthy and of the diseased appendix. It is based very largely upon original work consisting of cultural studies of appendices in sufficiently large series to make the results of significance. It is an important contribution to the subject of peritonitis of appendiceal origin.

College News Notes

Dr William Gerry Morgan (Fellow), Washington, D C, during the latter part of August was unanimously elected Dean of the Georgetown University School of Medicine by the University directors Dr Morgan will continue to serve as a Regent of the University, to which position he was appointed last June For many years, Dr Morgan has served on the medical faculty of Georgetown University Dr Morgan succeeds the late Dr John A Foote, who died several months ago Dr Morgan is the member of the Board of Governors of the American College of Physicians representing the general profession of the District of Columbia

At a recent meeting of the Board of Managers of the Goshen Hospital, Goshen, N. Y, Dr Louis F Bishop (Fellow) was appointed consulting cardiologist of the staff of consultants of the Goshen Hospital

Dr E J G Beardsley (Fellow), Philadelphia, addressed the Lehigh County Medical Society at Allentown, Pa, September 8, on "The Importance of Routine in Medical Diagnosis"

Dr. Roy C Mitchell (Fellow), Mount Airy, N C, presented a paper on the "Early Diagnosis of Carcinoma of the Stomach" at the meeting of the Eighth District Medical Society of North Carolina, October 2

The Inter-state Postgraduate Medical Association of North America held its annual meeting at Milwaukee, October 19-23, under the presidency of Dr. Henry A. Green (Fellow), Boston, Mass

Dr. Ed. H. J. (Fellow), Milwaukee, Secretary of the above Society

Under the Presidency of Surgeon General Hugh S Cumming (Fellow), U. S Public Health Service, Washington, D C, the American Public Health Association held its annual meeting in Montreal, Que, September 14-17

Dr J Feigenbaum (Associate) addressed the Montreal Clinical Society on September 9, 1931, upon the subject of "Constitution and Disease, Relating Particularly to Types Encountered in Peptic Ulcer, Gall Bladder Disease, Hypertension, and Exophthalmic Goiter"

Dr Frederick T Lord (Fellow), Boston, Mass, was elected president of the American Association for Thoracic Surgery at the fourteenth annual meeting held recently in San Francisco

Dr E J G Beardsley (Fellow), Philadelphia, addressed the Washington State Medical Association at Aberdeen, Washington, August 3, on "Cardiovascular Disorders of Every-day Practice" Dr Beardsley also held a clinic at the St Joseph Hospital, Aberdeen, on the morning of August 4

Dr. Howard L. Hull (Fellow), Elma, Washington, who has charge of the Oakhurst Sanitarium for Tuberculosis, acted as host to Dr Beardsley during his stay in the Evergreen State

Dr R. L. Hamilton (Fellow), Sayre, Pa, was among those who addressed the American Heart Association at its meeting in Philadelphia on June 6 Dr Hamilton's subject was "Precordial Pain Its Causes and Significance"

Dr Hyman I Goldstein (Associate), Camden, N. J, is the author of the article

"Sterile Live Maggots in the Treatment of Osteomyelitis and Tuberculosis Abscesses," which appeared in the July, 1931, issue of Medical Review of Reviews Dr Goldstein also has an article appearing in the September, 1931, issue—"Heredit-Familial Angiomatosis"

Dr James L. McCartney (Fellow), formerly Director, Bureau of Mental Hygiene, Connecticut State Department of Health, has been appointed psychiatrist with the New York State Department of Correction, and is stationed at the New York State Reformatory, Elmira, New York

Dr LeRoy S. Peters (Fellow), Albuquerque, N. M., presented a paper before the Los Angeles County Medical Society and the Hollywood Academy of Medicine on August 20

Dr Wann Langston (Fellow), Oklahoma City, Okla., has resigned as Superintendent of the University Hospital to become Professor of Clinical Medicine in the University of Oklahoma School of Medicine on a part-time basis. Dr Langston has opened his office at 502 Medical Arts Building for part-time practice in internal medicine

Dr Daniel E. S. Coleman (Fellow), New York, N. Y., is the author of an article, "Materia Medica—A Plea for Better Therapeutic Teaching," appearing in the August, 1931, issue of the Hahnemannian Monthly

Dr H. Beckett Lang (Fellow) has been appointed Clinical Director of the Marcy State Hospital at Marcy, New York

Dr Albert Warren Ferris (Fellow), after serving as Senior Assistant on the Staff of the Glen Springs, Watkins Glen, New York, for fifteen years in two terms of service, has retired from practice and resides at 111 N. Walnut Street, East Orange, N. J. Dr Ferris was previously President of the New York State Com-

mission in Lunacy, and Medical Editor of the International Encyclopedia

A medical clinic on Sero-fibrinous Pleurisy held by Dr. Carl V. Vischer (Fellow), Philadelphia, Associate Professor of Medicine at the Hahnemann Medical College, was published in the current issue of the Hahnemannian Monthly

Major Edgar Erskine Hume (Fellow), Medical Corps, U. S. Army, stationed at the Adjutant General's Office, State House, Boston, Mass., was under President Hoover's appointment, Secretary of the American Delegation to the International Congress of Military Medicine and Pharmacy at The Hague, Netherlands. There were ten United States delegates representing the U. S. Army, U. S. Navy, U. S. Public Health Service and the National Guard

Dr Fred M. F. Meixner (Fellow), Peoria, Ill., is the author of an article on "A Practical Classification of Heart Diseases," which appeared in the June, 1931, issue of the Peoria Medical News

Dr Harold G. F. Edwards (Fellow), Shreveport, La., is the author of an article on "A New Method for Studying Chest Films," appearing in the September, 1931, issue of Radiology

At a regular meeting of the Fulton County Medical Society on September 3, a bust of the late Dr. Elmore Callaway Thrash (Fellow), of Atlanta, Ga., was unveiled in the library of the Academy of Medicine at Atlanta.

Dr Horton Casparis (Fellow), Nashville, delivered a paper on "Allergy in Children" before the semi-annual meeting of the Southwestern Virginia Medical Society on September 24-25

Dr Francis H. Smith (Fellow), Abingdon, Va., also delivered a paper before the above meeting on "Coronary Disease as a Factor in Failing Myocardium"

Dr Samuel F. Thompson (Fellow), Kerrville, Texas, was re-elected President

of the Southwest Texas District Medical Society at its semi-annual meeting on July 13-14

Dr Waller S Leathers (Fellow), Dean, Vanderbilt University School of Medicine, Nashville, has been re-elected President of the National Board of Medical Examiners

Dr Luther C Davis (Fellow), Fairmont, W Va, has been appointed a member of the State Board of Nurses' Examiners to succeed the late Dr Harry M Hall (Fellow)

Dr William E Gardner (Fellow), Louisville, is Councilor for the Fifth District Medical Society, which was organized recently and is composed of physicians of Jefferson, Carroll, Trimble, Gallatin, Owen and Henry Counties (Kentucky) The new Society will meet twice a year

The following Fellows of the College were on the faculty of the Annual Summer Graduate Course at the Louisville City Hospital, held under the auspices of the Kentucky State Medical Association and the University of Louisville School of Medicine

Dr. Vugil E Simpson, Dr Philip F Barbour, and Dr Emmet F Horinc, all of Louisville

Dr Frank N Wilson (Fellow), Professor of Internal Medicine, University of Michigan Medical School Ann Arbor, presented four lectures on electrocardiographic studies, October 19-22 in a series held in the auditorium of Mount Sinai Hospital in connection with the graduate fortnight of the New York Academy of Medicine

The following Fellows of the College were on the faculty of the sixty-first annual session of the Colorado State Medical Association, September 15-17

Dr J. H. Smith, D. C. — Clinical Medicine
Dr J. H. Smith, D. C. — Clinical Medicine
Dr J. H. Smith, D. C. — Clinical Medicine

Dr Henry S Plummer, Rochester, Minn — "Adenomatous and Exophthalmic Goiter"

Drs Lorenz W Frank (Fellow) and Clough T Burnett (Fellow), both of Denver, took part in a symposium on the arthritides, which was presented at the above meeting

The International Association of Industrial Accident Boards and Commissions held its eighteenth annual convention October 5-9 at Richmond, Va There were two medical sessions on Wednesday, October 7, the one in the morning was held under the Chairmanship of Dr G H Gehrmann (Fellow), Medical Director of the E I duPont de Nemours and Company, Inc, Wilmington, Del The following Fellows of the College were speakers at the morning session, as indicated.

Dr Henry Field Smyth, Philadelphia,— "Should a Course in Industrial Medicine be Included in the Curriculum of Medical Schools?" This paper was discussed by Dr J Allison Hodges (Fellow), President of the Medical Society of Virginia,

Drs J Morrison Hutcheson, Richmond, and Francis H Smith, Abingdon, discussed a paper entitled "Settlements as a Therapeutic Measure"

The following Fellows of the College were speakers at the afternoon session, as indicated

Dr R Finley Gayle, Richmond, discussed a paper on the "Care and Treatment of Injured to Avoid Traumatic Neurosis,"

Drs Warren T Vaughan and Dean Cole, both of Richmond, together discussed a paper on the "Differential Diagnosis of Traumatic and Occupational Chemical Injuries"

The fourth Graduate Fortnight of the New York Academy of Medicine was held October 19-30 on the general subject of "Disorders of the Circulation" A number of the College's Fellows participated in the program

Dr Warfield T Longcope (Fellow), Baltimore—"Syphilitic Aortitis,"

Dr Lewis A Conner (Fellow), New York City—"Pericarditis — Diagnosis and Medical Treatment,"

Dr Alfred Stengel (Master), Philadelphia—"Relation of Heart Disease to Operations,"

Dr Harlow Brooks (Fellow), New York City—"The Heart of an Athlete,"

Dr William Sydney Thayer (Fellow), Baltimore—"Endocarditis"

Dr Edward O Otis (Fellow), Exeter, N H, who has been Governor of the American College of Physicians for the State of New Hampshire for several years, was recently honored by a special meeting at the headquarters of the Boston Tuberculosis Association, commemorating the fiftieth anniversary of his service in the field of tuberculosis. Dr Frederick T Lord (Fellow), and Dr John B Hawes, 2d, (Fellow), were speakers. Dr Otis is a former President of the National Tuberculosis Association, Honorary President of the Massachusetts Tuberculosis League and Professor Emeritus of Pulmonary Diseases and Climatology at Tufts College Medical School. He is eighty-three years of age, and still engaged in active work.

The Medical Society of Virginia held its sixty-second annual session at Roanoke, October 6-8, under the Presidency of Dr J Allison Hodges (Fellow), Richmond. The following Fellows participated, as indicated:

Dr Warren T Vaughan, Richmond—"Arthritis Treated as a Form of Bacterial Allergy,"

Dr D C Wilson, University—"A Survey of Mental Disease in Virginia,"

Dr Beverley R Tucker, Richmond—"A Suggested Program of Mental Hygiene for Virginia,"

Dr Walter B Martin Norfolk—"Value of the Hormone Test for Early Pregnancy,"

Dr H B Mulholland University—"Diabetes in Children and Young Adults,"

Dr J Morrison Hutcheson, Richmond—"Physical Factors in Coronary Occlusion,"

Dr William B Porter, Richmond—"Angina Pectoris Associated with Pernicious Anemia"

Dr Edward C Mason (Fellow), Oklahoma City, Okla, is the author of an article entitled "The Modern Treatment of Burns," appearing in the August issue of the Journal of the Oklahoma State Medical Association.

Dr Lewis B Flinn (Fellow), Wilmington, Del, is the first President of the Academy of Medicine of Delaware, recently organized.

The Medical Society of the State of Pennsylvania held its eighty-first annual session at Scranton, Pa, October 5-8 under the Presidency of Dr Ross V Patterson (Fellow), Philadelphia. Dr Elmer H Funk (Fellow), Philadelphia, as Chairman of the Committee on Scientific Work, presented the program. Dr William H Mayer (Fellow), Pittsburgh, was installed as the new President for the coming year.

Fellows of the College who offered papers are listed below:

Dr Roy R Snowden, Pittsburgh—"Report of a Case of Osteomalacia,"

Dr George R Minot, Boston—"The Treatment of Anemia,"

Dr Sydney R Miller, Baltimore—"Contemporary Fads and Fallacies, Therapeutic and Diagnostic which Reflect Dangerous Professional Credulity"

Dr Henry K Mohler, Philadelphia—"Auricular Fibrillation—an Analysis of 220 Cases,"

Dr O H Perry Pepper Philadelphia—"Malignant Hypertension Simulating Brain Tumor"

Dr Willis F Manges Philadelphia—"Pulmonary Disease as the Result of Nasal Accessory Sinus Infection"

Dr Louis Humm Baltimore II
Diagnosis of Obsolete Fever

Dr Charles C Wolferth, Philadelphia—"Indications for the Use of Laboratory Methods of Cardiovascular Diagnosis,"

Dr Edward L Bortz, Philadelphia—"Diffuse Gastric Hemorrhage with Special Reference to Dieulafoy's Ulcer,"

Dr Edgar M Green, Easton—"General Atelectasis of the Right Lung with the Heart Displaced to the Right of the Median Line and Left-Sided Pneumothorax,"

Dr John D Wilson, Scranton—"A Case of Xanthomatosis,"

Dr George Morris Piersol, Philadelphia—"Granulopenia,"

Dr Thomas Fitz-Hugh, Jr, Philadelphia—"Leukemoid Blood Reactions,"

Dr David Riesman, Philadelphia—"The Preoperative and Postoperative Treatment of Surgical Diseases of the Kidney from the Medical Standpoint,"

Dr E Bosworth McCready, Pittsburgh—"Relation of Endocrines to Juvenile Psychoses"

Dr Orlando H Petty (Fellow), Philadelphia, has been appointed Director of Public Health of the City of Philadelphia to fill out the term of Dr Andrew Carns, recently deceased

Dr Beaumont S Cornell (Fellow), Fort Wayne Ind, addressed the eighty-second annual session of the Indiana State Medical Association, which was held at Indianapolis September 23-25 on "Critical Review of Hypertension"

Dr Roscoe L Sensenich (Fellow) South Bend, Ind participated in a symposium on gastrointestinal diseases

Dr Walter S Leathers (Fellow), Nashville, was among the speakers at a conference of public health workers on Kentucky, Tennessee and Missouri, held at Louisville, Ind, September 21. Dr Leathers gave the paper "Medical Aspects of Tuberculosis in the South"

Drs Wardner D Ayer (Fellow), Syracuse, and Clayton W Greene (Fellow), Buffalo, are members of a Committee on Infantile Paralysis appointed by the President of the Medical Society of the State of New York to assist the Chairman of the Standing Committee on Public Health in devising means by which family physicians may aid in the control of the present epidemic

Dr Lewis J Morrman (Fellow), Oklahoma City, was appointed Dean of the University of Oklahoma School of Medicine

The thirty-seventh annual meeting of the Utah State Medical Association was held at Salt Lake City, September 9-11, under the Presidency of Dr William L Rich (Fellow). The following members of the College appeared on the program

Dr William C MacCarthy (Fellow), Rochester, Minn—"Why Cancer is so Frequently Hopeless,"

Dr Walter E Leonard (Associate), Los Angeles, Calif—"The Surgical Diabetic"

Dr Julius H Hess (Fellow), Chicago, addressed the American Dietetic Association, held at Cincinnati, October 19-21, on "Infant Feeding"

Drs Noble Wiley Jones (Fellow), Portland and Ralph C Maston (Fellow), Portland, addressed the Idaho State Medical Association's meeting on "Chronic Sinus Infection in Relation to Systemic Disease" and "Treatment of Impyema," respectively

Dr Frederick Tice (Fellow), Chicago, was recently appointed President of the Board of Directors of the Municipal Tuberculosis Sanatorium

Dr Walter M Simpson (Fellow), Dayton, and Dr Paul A O'Brien (Fellow), Rochester, Minn, delivered addresses on "Chronic Liver (Pneumonia) and Arterio-

ceral Syphilis', respectively, before the one hundred and eleventh meeting of the Michigan State Medical Society, held at Pontiac, September 22-24

The following Fellows of the College were among the guest speakers at the all-day session of the Northwestern Ohio Medical Association, Marion, Ohio, October 6

Dr Nathan S Davis III, Chicago—"Cardiac Infarction without Pain,"

Dr Julius H Hess, Chicago—"A Study of Premature Infants"

Acknowledgment is made of the following gifts of reprints by members to the College Library

Dr Miles J Breuer (Fellow), Lincoln, Neb—1 reprint,

Dr A B Brower (Fellow), Dayton, Ohio—1 reprint (with Dr Walter M Simpson (Fellow), Dayton, Ohio),

Dr Robert Chobot (Fellow), New York, N Y—1 reprint,

Dr A Morris Ginsberg (Fellow), Kansas City, Mo—1 reprint,

Dr, George B Lake (Associate), Highland Park, Ill—14 reprints

OBITUARIES

DR LEONARD M MURRAY

Dr Leonard M Murray died suddenly at his home in Toronto, Saturday, August 8, 1931, under tragic circumstances. His family was abroad and unable to reach Toronto in time for the funeral which was held Thursday, August 13

Dr Murray was born in Truro, Nova Scotia, 1875. He graduated from McGill University Faculty of Medicine in 1900. He was sometime Provincial Pathologist of Nova Scotia and Professor of Pathology, Halifax Medical College, later Attending Physician, Halifax Children's Hospital and Professor of Medicine, Dalhousie University (Halifax). He served overseas during the War, at first in France and later at Bushy Park, England the Canadian Hospital for cardiovascular cases. In 1919 he came to Toronto as Consultant in Diseases of the Cardiovascular System, for what is now known as the Federal Department of Pensions and National Health. He was appointed to the Department of Medicine, University of Toronto, and to the Staff of the Toronto General Hospital for

the years 1919 to 1928, when he resigned largely on account of the pressure of work due to private practice and the departmental work at Christie Street Hospital

During his professional life he did postgraduate work in England, the United States, and abroad. He was a Fellow of the American College of Physicians and served on the Board of Regents for many years. He was elected a Fellow of the recently formed Royal College of Physicians and Surgeons of Canada in 1931. At the time of his death he was, in addition, a member of the Toronto Academy of Medicine, the Ontario and Canadian Medical Societies, the American Therapeutic Association and the Association for the Study of Internal Secretions. His later publications dealt entirely with diseases of the cardiovascular system.

The above is but a brief outline of his professional career. His advent to Toronto was a happy one for those of his friends who lived here. Strong bands of esteem and affection quickly were formed not only amongst the members of the medical profession but

as well amongst those who sought his advice and all who came in contact with him. There are those, not necessarily classed as cynics, who regard this as a real accomplishment. He was a member of The York Club and The Lambton Golf Club.

Saturday, August 8, was warm. Dr. Murray had planned a fairly full day, which was begun by meeting two distinguished guests at the station early in the morning. This was followed by a foursome at golf during which he played a good game. That he nevertheless felt under some distress is evidenced by the fact that he took an early morning mixture of soda bicarbonate, repeating this after his return to his house in the early afternoon. He apparently refused to do more than rest for a short time before again driving to the hospital to see a patient. After his return from the hospital, he was in evident distress and to those of us who have learned his philosophical outlook on life, it is evident that he more than suspected his real condition. This time he took a stimulant but shortly after insisted upon receiving his guests who had been elsewhere for tea. As all were tired and the day hot, a short rest was welcomed before dressing for a dinner which was to take place later at The York Club. The chance call of one of the guests as to the time of dinner led to the discovery of his collapse and death but a few moments after he had seen that his house guests were comfortable. In the crucial few hours before he died and while under distress, he behaved rather than medical judgment sought him, as to the latter

sorrow of many. The diagnosis would seem to be coronary thrombosis.

It is of professional interest to record that four electro-cardiographs had been taken, the last being in February, 1931. In his own phraseology, these fell within the accepted normal, except for a slight left ventricular preponderance. A more definite indication is given in that but a few days previously, in talking over the effect of golf on hot days with one of his colleagues, a slight amount of discomfort was mentioned.

In the delicious intimacy of an evening's relaxation amongst a few friends, which he so thoroughly enjoyed, Dr. Murray had more than once declared that when he "went" he hoped he would go quickly, that he would be buried without "fuss or fumble" and "be forgotten." The first part of this wish has been fulfilled, the last, for his colleagues, for those who sought his advice or held his friendship, is impossible. His personality, charm, humor, sympathy and ability will in their memory endure for all time.

(Furnished by A. H. W. Caulfield M.D., F.A.C.P., Toronto.)

DOCTOR ELMORE CALLAWAY THRASH

Dr. Elmore Callaway Thrash (Fellow) died at Boulder Crest, Atlanta, Ga., on June 22, 1931, in his sixty-fifth year. Although the end came suddenly, it was not unexpected, as six months before he had developed a partial occlusion of a coronary artery. As an evidence of his devotion to duty and of his loyalty to his friends, shortly before he died he

attended the recent meeting of the American Medical Association as a member of the House of Delegates in order to serve as the representative of the medical profession of Georgia. On his return he was confined to his home up to the time of his death.

Dr Thrash was born in Meriwether County, Georgia on February 20, 1867. He was graduated with honors from the University of Louisville School of Medicine in 1891. He served as president of the Fulton County Medical Society and also the Medical Association of Georgia. In his early life Dr Thrash read a paper before the Medical Association of Georgia urging the establishment of a State Board of Health. This attracted so much attention that it was published in pamphlet form and distributed among the voters of the State. Soon after this the very efficient Georgia State Board of Health was organized.

In 1905 Dr Thrash was elected Professor of Pathology and Bacteriology in the Atlanta School of Medicine and he served in this capacity until 1914, in which year he was elected Professor of Diseases of the Chest in the Atlanta Medical College.

Dr Thrash always took a leading part in the various activities of the local, state and national medical associations. At these meetings he always stood for what was right, even if he stood alone. He read numerous papers dealing with pathology, bacteriology and internal medicine before medical societies throughout the nation and his views always commanded attention. Being a fluent speaker, having an alert mind, and a dis-

tinguished personality—which was unforgettable—he was probably better known than any other physician in the South.

On September 3, 1931, the medical profession of Atlanta presented to the Library of the Fulton County Medical Society a marble portrait bust of Dr Thrash as a tribute to his services to the medical profession and to mankind.

(Furnished by Jas N Brawner, M D, Atlanta, Ga.)

DOCTOR (LT COL) WILLIAM STEPHENS SHIELDS

Lt Col William Stephens Shields (Fellow), Medical Corps, U S Army, died, August 6, 1931, at the Letterman General Hospital, San Francisco, after an illness of about a year, aged 49 years.

Lt Col Shields was born at Washington, Georgia, and after completing his preliminary education, attended the Medico-Chirurgical College at Philadelphia, from which he received the degree of M D in 1906. He pursued postgraduate study at the Army Medical School and Columbia University, and was later a Fellow in Medicine under the Mayo Foundation. He was the author of a number of publications appearing in the Military Surgeon. He was a Fellow of the American Medical Association and was elected a Fellow of the American College of Physicians on November 17, 1928.

DR HENRY LALE WINTLER

Dr Henry Lale Winter (Fellow) Newburgh N Y died of heart disease July 29 1931, aged 63 years.

Dr Winter was born in Brooklyn, July 7, 1868, attended Brooklyn High School and later received his medical degree from New York University in 1892. He pursued postgraduate study in Munich, Nancy and Paris. He formerly held appointments as instructor in neurology at the University and Bellevue Hospital Medical College, associate in anthropology at the Pathological Institute of the New York State Hospitals for the Insane, and attending neurologist at the University and Bellevue Clinic. Dr Winter served during the World War, he was formerly president of the Board of Education of Cornwall. At the time of his death, he was consulting neurologist to Cornwall and St Luke's Hospitals.

Dr Winter was ex-vice president and ex-president of the Orange County Medical Society, a member of the Medical Society of the State of New York, a Fellow of the American Medical Association, and a member of the American Association for the Advancement of Science. He had been a Fellow of the American College of Physicians since April 10, 1917. He was the author of many articles, published in leading medical journals.

DR EDWARD P. SCHATZMAN

Dr Edward P. Schatzman (Associate), Pittsburgh, Pa., died July 27, 1931, of heart disease, aged 55 years. Dr Schatzman was a graduate of Western Pennsylvania Medical College, Pittsburgh in 1909. He was a member of the Nu Sigma Nu Fraternity, Allegheny County Medical So-

ciety, Pennsylvania State Medical Association, and the American Medical Association. He had been an Associate of the American College of Physicians since April 3, 1923. His practice had long been limited to internal medicine and diagnosis.

DR JOSEPH WITHAM YOUNG

Dr. Joseph Witham Young (Associate), Toledo, Ohio, died July 14, 1931, aged 54 years.

Dr Young received his B.S. degree from Cornell University in 1899 and his M.D. degree from Columbia University College of Physicians and Surgeons, 1903. From 1905 to 1906, he did postgraduate study in pathology and in internal medicine at the University of Berlin, and during 1919 in internal medicine at Harvard University Medical School. From 1906 to 1911, Dr Young resided in New York City, where he was assistant to the Out-patient Department of Bellevue Hospital and assistant in the Medical Department of the Vanderbilt Clinic. He had been a member of the staff of the Robinwood Hospital of Toledo since 1918.

Dr Young was a member of the Phi Delta Theta medical fraternity, a member and ex-chairman of the medical section of the Academy of Medicine of Toledo, a member of the Ohio State Medical Association, Northern Tri-State Medical Association, Northwestern Ohio Medical Association, and a Fellow of the American Medical Association. He had been an Associate of the American College of Physicians since April 3, 1922.

The Vital Hormone of the Adrenal Cortex*†

By FRANK A. HARTMAN, A.M., Ph.D., BYRON D. BOWEN, M.D., F.A.C.P.,
GEO. W. THORN, M.D., and CLAYTON W. GREENE, M.D., F.A.C.P.

IT HAS been known for many years that the adrenal glands are essential to life, but Wheeler and Vincent were the first to prove, at least in mammals, that the medulla was not essential. They found that as long as an adequate amount of cortex survived, destruction of all of the medullary tissue led to no ill effects.

The next step in the study of the cortex was the preparation of an extract containing the hormone. The cortex contains a sufficient amount of epinephrin to make the removal of the latter necessary, especially if the extract is to be concentrated.

In October, 1927, Rogoff and Stewart described the results obtained with two preparations, one a simple 0.9 per cent NaCl extract and the other a glycerol extract of the cortex. These methods do not eliminate the epinephrin and therefore definitely limit the amount of material which can be injected, on account of the epinephrin content of the extracts produced. Their report did not give the average survival of treated animals as compared with controls, although of thirty dogs treat-

ed six lived longer than the longest of the control animals.

In the same month Hartman, MacArthur and Hartman described a method for preparing an epinephrin-free cortical extract. With such an extract it was possible to increase markedly the survival period of completely adrenalectomized cats, the average survival period of all of the treated animals being twenty-one days as compared with six days for the untreated animals.

In March, 1930, Swingle and Pfiffner described a method of preparing a concentrated extract sufficiently potent to maintain the lives of adrenalectomized cats indefinitely. Their extract contained much epinephrin and inert material and was prepared by a long and complicated process.

In June, 1930, Hartman and Brownell described a simpler process for the preparation of a concentrated cortical extract. Their extract containing less than 1/100,000 epinephrin could be administered intravenously as well as subcutaneously. One patient has been injected subcutaneously four times daily for more than seven months without untoward results.

Experiments on animals have served as a basis for clinical work; therefore an outline of these results should precede the clinical studies.

†Presented at the Baltimore meeting of the American College of Physicians, March 26, 1931.

ANIMAL EXPERIMENTS

With the concentrated extract it is possible not only to maintain the lives of adrenalectomized animals indefinitely, but to enable such animals to live an apparently healthy existence (figure 1). One completely adrenalectomized cat was kept alive for 268 days and died because the extract was discontinued. Others have been kept alive for more than 150 days. This substance in the cortex which is essential to life has been called cortin.

Adrenalectomized cats treated with adequate cortin, eat well, gain in weight, play and fight. One female "came in heat" and became pregnant. The amount of extract required varies with the individual animal and also depends upon the stresses to which he is subjected. Until recently, in experi-

mental work upon cats, the adrenals have been removed in two stages a few days apart, because if both adrenals were removed at one operation the animal failed to make a good recovery and died in a few days. Now it is possible to remove both adrenals at one operation with excellent recovery if cortin is administered frequently. Such animals will apparently live indefinitely but they require much more cortin at least for a few weeks than those of the two-stage operation. We have removed both adrenals at one operation in three cats. At first the extract was given four times a day following bilateral adrenalectomy, then three times a day. The animals ate well and made a better recovery than many animals subjected to major operations not involving the adrenals. The

FIG. 1. Completely adrenalectomized cats kept in good condition by cortin.

reduction of extract caused loss of appetite and bloody feces in two, and bloody urine in the third. Increasing the extract caused complete recovery in all cases.

So far it has been impossible to produce overdosage phenomena.

By the administration of cortin one can revive adrenalectomized cats allowed to pass into the last stages of insufficiency preceding death. If the injections are intraperitoneal the effects begin to appear in less than an hour. If given subcutaneously it takes somewhat longer. One animal was allowed to go until there was marked prostration, dyspnea and muscular twitching. Intraperitoneal injection of cortin caused the disappearance of twitching and dyspnea within an hour, ten minutes later she was sitting up, forty minutes later she was eating. Recovery was complete.

Cortin appears to be essential for growth. If both adrenals are removed from young rats, a few continue to grow normally, some grow more slowly and others fail to grow at all, finally dying after days or weeks. Young adrenalectomized rats which are injected with adequate cortin all grow at about the normal rate. The females become pregnant and raise litters, then if the cortin is discontinued, some lose weight and die.

The operative wounds of adrenalectomy and other traumata heal slowly if an insufficient amount of cortin is administered but they heal normally if an adequate amount is given.

Cortin raises the resistance of adrenalectomized rats to bacterial toxins (Hartman and Scott, Perla and Marston-Gottesman). Seventy per cent

of the adrenalectomized rats injected with cortin survived a single dose of typhoid vaccine which killed all unprotected adrenalectomized rats. Cortin also protected adrenalectomized rats against increasing dosages of dead *Staphylococcus aureus*. The dosage had reached ten billions per day on the ninth day. At that time sixty per cent of the unprotected rats had died while all the treated ones were still alive and in fairly good condition.

Adrenalectomized animals are very sensitive to cold. When treated with an adequate amount of cortin, they resist cold almost as well as do normals. Two series of completely adrenalectomized rats of 20 and 19 rats respectively were exposed to a temperature which began at 56°F and gradually fell to 47°F in ten hours. One series had been injected twice daily with cortin, while the other series had been injected with the same volume of isotonic NaCl solution. Six normal rats were used as controls. Six hours after exposure to cold the average temperature (rectal) of the cortin-treated adrenalectomized rats was almost the same as that of the normals (98.8°F) while the average temperature of the NaCl-treated adrenalectomized rats was 91.8°F, excluding one that died. At the end of ten hours three more NaCl-treated rats had died while the average temperature of the remaining rats had fallen to 80.9°F. The temperature of the cortin-treated rats had fallen to 95.7°F as compared with 98.5°F for the normals.

The poor resistance to cold seems to be due to the inability to produce heat. We have been able to show that rats produce from 10 to 25 per cent less

heat after adrenalectomy. If, however, cortin is administered, heat production is maintained at almost normal levels.

The reduced heat production and lowered resistance to bacterial toxins are probably not specific but are merely manifestations of the reduced activity on the part of the body cells generally.

CLINICAL STUDIES

Since asthenia is one of the important manifestations of adrenal insufficiency, we have sought for a method of measuring it in the human.

Eigometer Test for Fatigue. In asthenia there is increased susceptibility to fatigue, although the muscular dynamic power may not decrease materially. Therefore the measurement of asthenia should test the threshold for fatigue rather than the strength of a single contraction. An eigometer can be used successfully to measure the fatigue threshold, provided certain precautions are observed.

The middle finger lifts weights swung by a chain over a pulley. The adjoining fingers on each side are supported in metal tubes while the hand is supported on a pad and held in place by a strap over the wrist. The working finger is connected to the chain by a leather thong or stall. The finger lifts the weight at every other beat of a metronome which is beating seconds. This is continued until the finger definitely fails to lift the weight up to a given mark. This end point is important and can be determined best by an experienced operator. The load chosen should be one that causes fatigue in about three to five minutes. It is

one test to another may be too large. If too light, the time required for the test is too long, in case marked improvement is subsequently shown. By not making tests too often improvement that might be brought about by training is avoided. The measure of fatigue is the work done (weight \times vertical distance raised \times number of contractions).

There seems to be less variation in the base level for fatigue in asthenic individuals than in some normal individuals.

For many years numerous workers have endeavored to relieve the symptoms of Addison's disease by the use of adrenal preparations. The earlier efforts have been without notable success, except that the Muirhead treatment has been somewhat effective in cases that were apparently not too severe. Within the past two years three groups of investigators have studied the effects of extracts of the adrenal cortex on clinical cases. Rogoff and Stewart in 1929 treated several patients with an extract administered by mouth. Improvement in symptoms occurred after several weeks of treatment. None of the cases reported seemed to be severe. In January, 1931, Rowntree, Greene, Swingle and Piffner reported their results in a number of cases of Addison's disease in which the extract prepared by Swingle and Piffner was administered subcutaneously or intravenously. The majority of their cases were benefited definitely. So far as we have been able to discover, no case has been treated in which there was complete or nearly complete adrenal insufficiency. We

in two cases of practically complete bilateral atrophy of the adrenal cortex and in a third case in which there appeared to be adrenal insufficiency of lesser degree

Case 1 A man of 24, a handy-man doing outdoor work for a gas company, was an athlete, specializing in basketball and baseball. In the winter of 1929-30 he noted fatigue in the evening, and he experienced gastro-intestinal upsets. These consisted of anorexia, nausea, and vomiting, and occurred with increasing severity and frequency during the succeeding spring

and early summer. In his previous history the only incident had been a febrile attack in 1928, which he said his family physician had diagnosed as "scarlet fever without the rash." Just previous to admission he had been ill for six weeks, showing weakness, epigastric distress, nausea, vomiting, and a loss of thirty to forty pounds in weight since the preceding winter. Upon admission to the hospital July 7, 1930, he was in a state of "collapse", irrational and nearly comatose (figure 2). His systolic blood pressure was 50 mm and his diastolic was 20 mm

FIG 2 Case 1 three days after admission to hospital

During the first twenty-four hours he received injections of salt solution, glucose and adrenalin subcutaneously, but was not improved. His legs twitched and his extremities were cold. During the second day he received the extract of 3200 grams of adrenal cortex which was given fractionally by frequent subcutaneous injections. On the third day he ate for the first time, seemed more alert, read a little, and did not sleep so much. The daily dose was then reduced to the equivalent of 500 grams of cortex. Gradual improvement took place (figure 3) and

the extract was diminished but on the twelfth day he had another relapse when he became almost as ill as he was upon admission. This relapse was occasioned by a further reduction in the extract. A second very severe case (Case 2) was admitted to the hospital at this time and it became necessary to divide the very limited supply of extract between the two, Case 1 receiving the larger portion. A large increase in the amount of extract brought his condition back to its former level of improvement (figure 4). Three subsequent relapses occurred, on the 55th,

July 14, 1930

FIG. 3. Case 1, 7 days after beginning treatment.

86th, and 110th days after the institution of treatment. Each was caused apparently by a reduction of the amount of extract. It appeared from clinical observation that the daily administration of the extract from 1000 to 1200 grams of cortex was necessary to prevent the recurrence of symptoms. Also it seemed that injections every six hours were more effective than dosages fifty per cent greater given every eight hours.

It is probable that the amount of cortical hormone needed to obtain improvement in complete adrenal insufficiency, such as Case 1 represents, is much greater than that required for less severe cases such as have been reported from other clinics. In consequence, any question of potency of cortical extracts should be postponed until trial can be made on similar or the same cases. Our dosage has been based upon grams of fresh cortex. Our present extract contains in each cubic centimeter the product obtained from fifty grams of fresh material, although the earlier extract used in the first weeks in Case 1 represented fifteen grams per c c. When the extract was discontinued it required about three days for the recurrence of nausea, vomiting and asthenia, likewise about three days were necessary for complete recovery to the former level of improvement after the readministration of the extract. This cycle corresponds to the observations on adrenalectomized animals that are treated with the extract.

The blood pressure ranged from 85 to 100 systolic except during the relapses when it fell varying degrees. The temperature was usually about 97.0° F.

The blood urea which was 120 mgm on admission, fell promptly under treatment, but always rose when insufficient extract was given, while the blood sugar fluctuated considerably, reaching the low point, about 75 mgm, during relapses (figure 5).

During the first six and one-half months of treatment his clinical condition remained unchanged except for the short periods of relapse. The pigmentation however, increased very decidedly. His appetite, weight, and ability to work on the ergometer without fatigue remained about constant. From this time on he made further improvement. On the 224th day he could do six times more work than at the initial test on the ergometer; he had gained ten pounds in weight; his appetite had increased and he volunteered the information, "I can now walk quite fast." Data on the findings and the progress in this case are shown in the accompanying chart. The gaps indicate periods when he returned to his home in a nearby town. During these times he gave himself the injections. His first return to the hospital was because of a relapse, the second was for further study. His basal metabolism varied from minus 7 per cent to minus 15 per cent. While under observation in the hospital, after being out for a few hours one evening he developed an upper respiratory infection which persisted for seven days, with slight fever the first day. On the eighth day he had a chill, vomited and his temperature rose to 105.0° F. It was quite obvious that he had had an extension of his respiratory infection. His leucocytes were 30,000 with 84 per cent polymorphonuclears. The extract was

FIG. 3. Case 1 forty-five days after beginning cortin

increased to the limit available but he died in twenty-four hours

Autopsy Findings (A detailed report of the autopsy findings is to appear in *Endocrinology*) Addison's disease with marked atrophy of both adrenals, weight 3.44 gms. Old calcified tuberculosis of the mesenteric lymph-glands, and fresh tuberculous hyperplasia of a few mesenteric, and especially periaortic, periportal and peripancreatic lymphnodes, and a few anterior mediastinal nodes. Fresh lobular pneumonia of the right lower lobe. Fresh hemorrhage in the pleurae of both lungs, especially the left, also in a less degree in the mucosa of the stomach. Pseudo-melanosis of the cecum and appendix. Slight atrophy of the pancreas. Very slight atrophy of the heart. Slight splenic tumor. Chief diagnosis Addison's disease.

Case 2 This was a married woman 41 years of age, housewife, admitted to the hospital July 16, 1930. In 1925, five years before her admission to the hospital, her neighbors stated that she did not look well, her skin showed dark and light areas. At that time she was feeling fairly well and able to do her housework.

One year later she was treated for acute cholecystitis.

In 1927 she began to feel quite weak, had a poor appetite, was very nervous and restless, and could not sleep well. Her skin became much darker with the areas of vitiligo more prominent. She was seen by her physician at this time. Her blood pressure was 72 mm Hg, systolic. Diagnosis of Addison's disease was made. She remained in bed for one year, after which time she was up for only short intervals. Her blood

pressure remained between 66 and 72 mm Hg, systolic, and she gradually became weaker.

One year ago she had pleurisy and was in bed five weeks, after that she would be up part of the time. Her appetite was capricious. During the six weeks before admission she was in bed continuously.

There was no pain in the abdomen, but nausea and vomiting were present.

Physical examination revealed an adult female who was fairly well nourished. The skin was diffusely pigmented and showed scattered areas of vitiligo. There was no adenopathy. The chest was clear. Heart beat was quick, regular, no murmurs. Abdomen was negative. Blood pressure 60 mm systolic and 48 diastolic. Several small areas of pigment on the base of the tongue. No pigment in vagina, anus or rectum.

Laboratory findings Blood glucose 116 mgm, blood urea N 52.4 mgm, blood chlorides 534 mgm, blood uric acid 4.45 mgm. Urine normal. Blood count mild secondary anemia.

While in the hospital her blood pressure varied between 66 systolic and 48 diastolic, and 44 systolic and 28 diastolic. She became weaker, was nauseated and had some vomiting, epigastric pain, numbness and coldness in arms and legs. Before death which occurred three days after admission and two days after beginning treatment, pain in her legs was severe.

Autopsy Findings Pigmentation and vitiligo of skin, extreme atrophy of both adrenals, slight generalized passive congestion, healed tuberculosis of both apices, no active process, brown atrophy of the heart, recurrent chole-

cystitis, chronic lymphadenitis of lymph nodes of hilum of liver and pancreatic group, marked lymphoid infiltration and hyperplasia of thyroid

We believe that this patient should have received many times the amount of cortical extract that was administered to her but there was no more available

Case 3 A woman of 56 years who had had increasing fatigue and weakness for the past six years was admitted to the hospital Nov 19, 1930, for observation. She had been considered a case of hypothyroidism since 1921 and treated with thyroid which she stated brought about some improvement. Her blood pressure had been low during this period of observation. She also stated that brownish spots had appeared on her body during this time, but that her skin had always been dark. Three years before admission her physician had made a diagnosis of mild Addison's disease. She had lost some weight. Her blood pressure was 90 systolic and 60 diastolic. Her basal metabolism was low on several determinations—about minus 28 per cent. There was no pigmentation of the mucous membranes. She was under observation in the hospital for nine days before cortical extract was started during which time her ability to work on the ergometer without fatigue was established. Cortical extract was given twice daily subcutaneously for eight days, not including three days when it was omitted. Her ability to do work on the ergometer without fatigue was gradually increased, reaching a maximum of 2000 gm. work on the ergometer during the last day of treatment. During the next three days the extract was discontinued and her ability to do work on the ergometer without fatigue was gradually decreased, reaching a minimum of 500 gm. work on the ergometer during the last day of treatment.

mained unchanged. After discharge from the hospital she was without treatment for fifty days, during which time her ability to work on the ergometer was two to three times greater than it had been before the institution of treatment. Thyroid, 0.12 to 0.18 gm daily, was then given until her basal metabolism was brought to normal, when her ergometer reading was eight times the original. Cortical extract was added to the thyroid medication daily for nine days and then omitted. Four days after the cortical extract was discontinued she could do thirty-eight times more work on the ergometer than originally (figure 6). The patient stated that she felt stronger when taking the combined thyroid and cortical extract, and showed distinct clinical improvement, with moderate increase in her blood pressure. This improvement, however, did not parallel the remarkable increase in her ergometer readings.

In a potent cortical extract we possess a substance which may perhaps serve as a therapeutic test in Addison's disease and which possibly may be of value in testing and treating other forms of adrenal insufficiency. Numerous investigators have used adrenal preparations in the treatment of hyperthyroidism. Shapiro and Marmar reported the beneficial effect of a glycerol extract of the adrenal cortex in a case of Graves' disease. This was administered by mouth.

A boy of 19 years with clinical hyperthyroidism, who had never received iodine, rested for three weeks in the hospital before treatment was started. During this time his basal metabolism remained between plus 25 and plus 35

per cent on several determinations Cortical extract was then given daily for eighteen days. During this period he became able to do twice as much work on the ergometer as he had been able to do during the initial rest period. After the extract was discontinued, this ability to work increased to three times. There was no essential change in his basal metabolic rate. In the cases of Graves' disease reported by Marine and his co-workers a drop in the basal metabolism did not occur until treatment had been going on for a much

longer period. Unfortunately treatment in our case could not be continued longer.

Experiences in the relief of muscular fatigue led us to try cortin for the relief of two cases of muscular atrophy in men over fifty. In each case weakness began in the shoulder girdle. In each the muscular fibrillation disappeared during treatment. In one, an early case, the grip returned to normal in the hand affected. In the other, marked muscular cramps disappeared, to return when treatment was discon-

FIG 5 Chart showing various changes in Case 1

tinued. In a woman of 23 with the Landouzy-Déjérine type of muscular dystrophy treatment was followed by a marked increase in her capacity on the ergometer, and decidedly better rest during sleep

A few cases of marked post-infectious asthenia have shown clinical improvement following the use of cortin, with decided increase in capacity on the ergometer

SUMMARY

A potent cortical extract has been administered to two cases of practically complete adrenal insufficiency

In the first case it was of undoubted benefit Following its use the patient recovered from a very critical state That it kept him alive for nearly eight months was indicated by four definite relapses which followed its reduction or its discontinuance Readministration or increase of dosage in each relapse was followed by return to his former level He was making slow but definite improvement when bronchopneumonia caused his death

The period of treatment in the second case was obviously too short for observation to be of any value.

A third case, one of much less severity, has shown a remarkable increase in her ability to work without fatigue. Clinical improvement has not kept pace with this increase.

One case of hyperthyroidism has exhibited decided clinical improvement following the use of the extract alone.

Two cases of muscular atrophy and

one of muscular dystrophy have shown some improvement.

There is evidence that cortical extract reduces the asthenia which follows certain infections.

This study was aided by grants from the National Research Council and the Ella Sachs Plotz Foundation.

The Relation of the Parathyroid Glands to Calcium Metabolism*†

By HAROLD A. BULGER, M.D., and DAVID P. BARR, M.D., F.A.C.P.,
St. Louis, Missouri

THE profound influence of the parathyroid glands on calcium metabolism is apparent from both experimental and clinical studies. Removal of these glands results in a marked decrease in serum calcium, tetany and in retention of calcium in the body. By means of the parathyroid extract of Collip¹² it is possible not only to relieve the tetany but also to restore approximately normal conditions of calcium metabolism. Large doses of parathormone cause, in normal animals, hypercalcemia, hypotonicity of muscles, a great increase in the excretion of calcium in the urine, a deposit of calcium in the tissues and decalcification of bone. Furthermore Jaffe and Bodansky¹³ have recently shown that the injection of parathormone may form lesions resembling fibrous cysts in bone.

These changes from overdosage with parathyroid extract occur to a variable degree in different animals. Although several species are quite resistant the effect in man is well defined. The following following accidental complete

parathyroidectomy can be controlled over long periods. Hypercalcemia may be produced by large doses in individuals whose parathyroid glands are presumably normal. In Hunter's²² case of a house painter with lead poisoning, daily doses of 30 to 60 units of parathormone caused, in eleven days, a rise in serum calcium to 19.8 mg. A patient observed by Aub¹ demonstrates the source of the negative calcium balance in experimental hyperparathyroidism. This patient with otosclerosis was treated with parathormone for 42 days during which he lost 15 kilograms in weight, a change which would have accounted for 75 mg. of calcium if the loss of calcium had been derived from blood fluid and protoplasm. Actually he lost 170 grams of calcium which must have been derived from the bones.

Clinical hyperparathyroidism, presenting the identical features effected by injecting parathyroid extract is now recognized as a definite entity. It is encountered most often in association with the multiple lesions of osteitis fibrosa cystica (von Recklinghausen's disease of bone). In addition to bone cysts, giant cell tumor and general decalcification features which have been considered characteristic, there have been many cases of hyperplasia

*Presented at the 1935 Annual Meeting of the American Association of Endocrinologists, St. Louis, Mo., Dec. 1-4, 1935.

†Supported in part by a grant from the National Cancer Institute, U. S. Department of Health, Education and Welfare.

of tumor formation of the parathyroid glands, hypercalcemia, greatly increased calcium excretion in the urine, deposition of calcium in the tissues (the so-called metastatic calcification of Vitchow) and occasionally the formation of stones in the urinary tract. The simulation of experimental hyperparathyroidism is so striking that there is reason to believe that the entire picture of osteitis fibrosa cystica is secondary to the increased activity of the parathyroid glands. Whether or not this be true, operation has demonstrated in a number of cases how completely the clinical condition can be arrested by removal of parathyroid tumors of hyperplastic parathyroid tissue. The effect upon the level of calcium in serum is well shown by Table I which includes the cases of osteitis fibrosa cystica in which parathyroid tissue has been removed for therapeutic effect.

In 16 out of 18 cases one or more tumors of the parathyroid gland were removed. The removal of the parathyroid tissue not only lowered the level of the calcium in the serum and transformed the previous negative balance into a retention of calcium but stopped the progress of the disease and arrested the formation of bone cysts and tumors. Recalcification of bone and recession of the cysts and tumors has been demonstrated. The marked drop in serum calcium indicated by the table was observed soon after operation and in many instances, although not all returned after a few weeks to a normal level. In the case of Barrenscheen and Gold⁴ a normal sized gland imbedded in the thymus was taken away without beneficial effect on the patient's symptoms and without change in the calcium level of the serum. In DuBois's¹⁴ case, however, two normal looking parathy-

roid glands were removed with apparent clinical improvement

Although osteitis fibrosa cystica may be the only condition which can be called with any probability a primary hyperparathyroidism, there are other bone diseases which may at times present comparable disturbances of calcium metabolism. Multiple myeloma is a condition accompanied by a high degree of bone destruction and it has been noted frequently in roentgenological examinations that there is a marked decalcification and rarefaction even in those portions of bone which are not actually involved in the tumor process. Metastatic calcification with deposit of calcium in lungs, gastric mucosa and kidneys has also been noted in multiple myeloma. Bulger and Barr¹⁰ studied a patient presenting these associations, including hypercalcemia, a negative calcium balance and metastatic calcification in whom there was generalized hyperplasia of the parathyroid glands. Apparently a similar condition may also occur in metastatic tumor of bone. Klemperer²⁴, in 1923, reported a case in which a tumor of the parathyroid gland was found in association with carcinoma of the breast and osseous metastases. It, therefore, appears that we may have a state in which hyperparathyroidism is associated with obviously primary bone disease. The following cases are presented as examples of this clinical picture.

Case 27600 Barnes Hospital. This was a 65-year-old woman who had gradually increased pain in the back for three years. She had no other symptoms and began to lose weight. She had no other symptoms and began to lose weight. She had no other symptoms and began to lose weight.

weakness became a prominent feature. Physical examination revealed marked pallor and great emaciation. There was evident mental depression and confusion. The red blood count was 1,900,000 with 35 to 40 per cent hemoglobin and a slight leucopenia. The non-protein nitrogen was 63 mgm per cent. The x-ray of the spine showed a general loss of calcium throughout, and narrowing of the bodies of the second lumbar, and ninth and twelfth dorsal vertebrae. The bony texture was uniform and the intravertebral spaces preserved. The pelvis showed irregularly outlined areas of rarefaction, the calvarium, clean-cut skull defects with some areas of marked mottling, indicative of an invasive process of finer type. The patient's serum calcium ranged from 15.8 to 16.5 mgm per cent. Probably because of the kidney insufficiency the serum phosphate was elevated to 6.3 mgm per cent. The non-protein nitrogen was 63 mgm per cent and the phenolsulphonphthalein excretion was only about 5 per cent. The urine showed a slight amount of albumin and a few granular casts. The urine also showed Bence-Jones' protein. The pathological process in the bones as revealed by x-ray was evidently malignant disease which was considered more like multiple myeloma than metastatic carcinoma. X-ray examination of the gastrointestinal tract and pyelograms of the urinary tract were negative. This patient died at home and no autopsy was made.

Case 27621 Barnes Hospital. This patient was a moderately obese woman, 49 years old, who had been bothered with chronic constipation. For about a year she had had dull pains in the lumbar and sacral regions and later in the left lower quadrant. She had recently shown evidence of mild diabetes mellitus. About three weeks before admission she collapsed from great weakness and began to have spells of nausea and vomiting. In the hospital her chief complaint was generalized weakness although at times the pain in her back was quite severe. She showed evidence of some loss of weight. The heart was moderately enlarged, regular and a little rapid. There was slight depression of the jugular venous pressure. The blood pressure was 170/120. The red blood count was 2,000,000 with 35 per cent hemoglobin.

FIG 1 Spine of Case 25209 showing general decalcification with narrowing of the bodies of the ninth and twelfth dorsal and second lumbar vertebrae

FIG. 2. Skull of Case 25209 showing clean cut bony defects with some areas of finer mottling

per cent hemoglobin. The non-protein nitrogen varied from 50 to 67 mgm. The urine contained a slight amount of albumin and numerous white blood cells. Bence-Jones protein was never demonstrated. X-ray examination of the spine showed a marked decrease in density throughout the bones and there was a symmetrical collapse of the fourth and sixth dorsal vertebrae. The third and sixth dorsal vertebrae also showed considerable decrease in bony texture indicating that the disease process was more generalized than the collapse of the fourth and sixth vertebrae. The skull was also examined and showed a decrease in density throughout the bone. The frontal bone showed a symmetrical collapse of the central and lateral regions. The maxilla and mandible also showed a decrease in density. The overall appearance was that of a generalized osteoporosis.

tract did not reveal anything that could be considered a primary site. This patient's serum calcium ranged between 16.5 and 18.3 mgm per cent, phosphate between 4.0 and 4.9 mgm per cent. Further studies showed she was on a slightly negative calcium balance. The amount of calcium excreted in the urine was greater than would have been expected with the demonstrated degree of kidney insufficiency. Since discharge from the hospital he has been taking slowly. Case 22810. Bone. Hospital. This was a 40 year old male who had been treated for a chronic depressive psychosis for many years. He had a family history of tuberculosis. X-ray examination of the skull showed a symmetrical collapse of the frontal bone. The maxilla and mandible also showed a decrease in density. The overall appearance was that of a generalized osteoporosis.

FIG 3 Spine of Case 27621 showing general decalcification with collapse of the body of the fourth dorsal vertebra and slighter changes in third and sixth dorsal vertebrae

FIG. 4 Calvarium of Case 27621 showing multiple areas of rarefaction

calcification in the pelvis. Later consideration showed that the lesser trochanter of the right femur could not be seen (figure 5). In three months she was again complaining of the same pains in the right leg. X-rays then revealed that in this short interval an extraordinary degree of decalcification had occurred with rarefaction of the head and neck of the femur and with loss of bone substance in the neck of the right femur and the upper portion of the acetabulum (figure 6). Similar changes were noted in the iliac crests, the heads of the right ribs and the lower portion of the sternum. There was a fracture of the neck of the right femur with the lower end of the shaft. X-rays also showed that the pelvis had not been calcified previously. She died before a

marked hypercalcemia, the serum calcium ranging from 13.5 to 15.1 mgm per cent, low serum phosphate varying from 2.5 to 2.6 mgm per cent. Shortly after x-rays were taken she fractured her right femur, an injury which she survived for only five months. Autopsy revealed hypernephroma involving the adrenal, both kidneys, the femur and pelvis. The acetabulum was entirely destroyed and there was a large tumor mass extending into the pelvis from the right side and pressing on the rectum. It is most unfortunate that permission to examine the parathyroid glands was not obtained. Of particular interest in the post-mortem examination were the kidneys which showed a deposit of calcium about the tubules similar to metastatic calcium deposits.

FIG 5 X-ray of right hip of Case 22810 taken at time of admission to the hospital and showing abnormal area of calcification in pelvis, absence of lesser trochanter but little other evidence of decalcification or destruction

Fig. 6. A large, dark, irregularly shaped mass, possibly a tumor or lesion, is visible on the right side of the image. The mass has a bright, circular highlight in its center. The background is light and grainy. In the lower-left corner, there is a small, dark, vertical, elongated shape, possibly a finger or a tool, and a small black triangle in the bottom-left corner.

Parathyroid hyperplasia has been demonstrated by Erdheim¹⁷ in spontaneous rickets in animals, and by Pappenheimer and Minor³⁰ in rickets in children. Enlargement of the parathyroid has been recorded in osteomalacia. These findings raise the question as to the relation of the parathyroid glands to the disturbed calcium metabolism of these conditions. One finds in rickets and osteomalacia abnormalities of calcium metabolism quite distinct from those characteristic of hyperparathyroidism. In contrast to hyperparathyroidism one finds in both conditions a tendency toward a low serum calcium and tetany. Both have an increased elimination by the gastro-intestinal tract but very small amounts of calcium in the urine. Therefore, it does not appear that there is any direct relation between the abnormalities presented and an increased activity of the parathyroids. Some of the abnormali-

ties in rickets and osteomalacia is not a primary factor but is of the nature of a compensating mechanism. It might be noted that parathormone will relieve the tetany of both conditions and we have noted the transformation of a negative into a positive calcium balance in a case of osteomalacia on administration of parathormone.

The principal condition responsible for the development of rickets and osteomalacia is a deficiency of ultra-violet radiation and vitamin D. The relationship between these factors and the activities of the hormone of the parathyroid glands is so intimate that their functions in relation to calcium metabolism cannot well be discussed separately. The action of large amounts of vitamin D (irradiated ergosterol) is strikingly like parathyroid extract. It causes an increase in calcium in the serum, metastatic calcification and an increased excretion of calcium in the

Parathyroid hyperplasia has been demonstrated by Erdheim¹⁷ in spontaneous rickets in animals, and by Pappenheimer and Minor³⁰ in rickets in children. Enlargement of the parathyroid has been recorded in osteomalacia. These findings raise the question as to the relation of the parathyroid glands to the disturbed calcium metabolism of these conditions. One finds in rickets and osteomalacia abnormalities of calcium metabolism quite distinct from those characteristic of hyperparathyroidism. In contrast to hyperparathyroidism one finds in both conditions a tendency toward a low serum calcium and tetany. Both have an increased elimination by the gastro-intestinal tract but very small amounts of calcium in the urine. Therefore it does not appear that there is any direct relation between the abnormalities presented and an increased activity of the parathyroids. Some of the abnormali-

ties are like those found in hypoparathyroidism but the bone pathology and negative calcium balance are distinctly different. It might be noted that parathormone will relieve the tetany of both conditions and we have noted the transformation of a negative into a positive calcium balance in a case of osteomalacia on administration of parathormone.

The principal condition responsible for the development of rickets and osteomalacia is a deficiency of ultra-violet radiation and vitamin D. The relationship between these factors and the activities of the hormone of the parathyroid glands is so intimate that their functions in relation to calcium metabolism cannot well be discussed separately. The action of large amounts of vitamin D (irradiated ergosterol) is strikingly like parathyroid extract. It causes an increase in calcium in the serum, metastatic calcification and an increased excretion of calcium in the

urine Absence of vitamin D may cause a decrease in serum calcium and tetany Several authors have suggested that vitamin D exerts its influence by directly stimulating the parathyroid glands Morgan and Garrison²⁷ have demonstrated, however, that there is actually a variation in effectiveness of parathormone depending upon the amount of vitamin D in the body. The experiments of Rosello and Petrillo³³ have indicated that after the absence of radiant energy for some time parathyroid extract is relatively inactive Again, it has been shown that after removing the parathyroid glands, vitamin D is much less active It appears, indeed, that the more thoroughly parathyroid tissue is removed, the less effective is vitamin D Taylor, Branion and Kay³⁷ showed that when complete eradication of parathyroid tissue is assured by removing all tissue of the region including the thymus, huge doses of irradiated ergosterol were required to raise the calcium of the blood Thus some doubt is cast upon its efficacy It should be noted, however, that Pappenheimer²⁹ has demonstrated that cod liver oil and irradiated ergosterol in therapeutic doses are antirachitic in the absence of the parathyroid glands

The clinical diagnosis of hypoparathyroidism may be indicated by the history of thyroidectomy and the occurrence of tetany In the opposite condition of hyperparathyroidism, tumors in the region of the thyroid have occasionally been palpated but are easily confused with adenomata of the thyroid gland Ordinarily disturbances in calcium metabolism offer the best evidence of abnormal parathy-

roid function and consist of changes in the level of serum calcium, in the excessive excretion of calcium in the urine, in decalcification of the skeleton and deposit of calcium in the tissues Metastatic calcification can be discovered only at autopsy while the determination of calcium balance is much too cumbersome, difficult and time-consuming to be applied as a clinical test The level of serum calcium remains, therefore, as the most readily ascertainable diagnostic method It is of interest to consider to what extent disturbances in the level of serum calcium reflect changes in parathyroid function and to inquire what factors other than the parathyroids may influence calcium values

It is important to emphasize the remarkable constancy of the serum calcium and that such an adjustment to a definite level is quite necessary because fluctuation in the concentration of calcium may cause profound changes in many physiological processes The activity of the parathyroid glands appears to be concerned, primarily, with this regulatory mechanism It is surprising that administering large quantities of calcium by mouth may have little or no influence on the amount of calcium in the blood After administering calcium salts intravenously the calcium in the blood promptly returns to normal Rapid destruction of bone may cause no rise in serum calcium With extensive malignant disease of bone, after comminuted fractures and with bone atrophy from disuse, serum calcium may be quite normal

Other factors may influence the level of calcium in the blood Aside from the fluctuations of serum calcium re-

lated to vitamin D or parathyroid activity, the two factors which have a significant influence on calcium are the concentrations of serum phosphate and serum protein. The calcium will rise and fall directly with the protein although the changes due to this factor are not great. Conditions producing a high serum phosphate, however, may be attended by a considerable reduction in the calcium. This phenomenon is most commonly seen in chronic nephritis with phosphate retention. It should also be noted that low serum calcium and even tetany may be associated with chronic diarrhea.

While the estimation of serum calcium is of undoubted diagnostic importance in indicating hyperparathyroidism, it appears that there may be an increased activity of these glands with an increased excretion of calcium and a large amount of calcium in the urine without obvious rise in the serum calcium. Aub¹ notes that 50 units of parathormone may not markedly influence the serum calcium level of a normal individual, while approximately doubling the excretion. Three of the cases included in Table I had relatively normal serum calcium although they were undoubtedly examples of clinical hyperparathyroidism and responded typically following the removal of parathyroid tumors. The bone lesions similar to those of clinical hyperparathyroidism which Jaffe and Bodansky²³ have apparently produced in animals are not necessarily accompanied by any increase in the serum calcium. It appears that patients with hyperparathyroidism who develop marked kidney insufficiency may have enough phosphate retention in the

blood to maintain a normal serum calcium. Bulger, Dixon and Barr¹⁰ have described in detail their experiences in reducing calcium to normal in two patients with hyperparathyroidism by administering phosphate solutions by mouth. This undoubtedly did not change the activity of the parathyroids but produced the effect by increasing the phosphate in the blood.

Hypercalcemia was noted clinically by Hess and Lewis¹⁹ in children who were receiving relatively large amounts of the irradiated ergosterol but it seems unlikely that this would be encountered in the average clinical experience and under the circumstances would hardly be confused with hyperparathyroidism. The occurrence of high serum calcium reported in gout and chronic arthritis has not been confirmed. High serum calcium was noted by Brown and Roth⁹ in polycythemia, but Benedict and Turner⁷, in a study of nine cases, did not find these high values. In three cases of polycythemia observed in this clinic the calcium was normal. It seems doubtful that any factors of clinical importance other than an increased activity of the parathyroids will cause a definite and continuous elevation of the serum calcium.

CONCLUSIONS

The influence of the parathyroid glands on calcium metabolism is apparent not only after removal of the parathyroids and the administration of parathyroid extract but also in clinical hyperparathyroidism a condition which appears most often in association with osteitis fibrosa cystica but also with multiple myeloma and metastatic tumors of bone.

The level of serum calcium is the best index of parathyroid function and is of such diagnostic importance that its use as a test should be applied in all cases with general disease of bone and in all conditions in which there may be a disturbance of calcium metabolism. The serum calcium, however, does not always reflect either disturbances of calcium metabolism or changed activity of the parathyroid glands. It may be normal even with

marked disturbances of calcium metabolism. In evident hyperparathyroidism it appears that serum calcium may occasionally be within normal limits. Low serum calcium may be due to a lack of vitamin D or to an increase of phosphate in the serum. These conditions, however, are not likely to be confused with hypoparathyroidism. Hypercalcemia usually indicates an increased activity of the parathyroid glands.

The Etiology and Treatment of Diabetes Insipidus*†

By T B FUTCHER, M B , F A C P , *Baltimore, Md*

THE chief purpose of this paper is to recount briefly the historical development of our knowledge concerning the etiology of diabetes insipidus up to the present time

According to Hirsch, the earliest account of a sweet taste of the urine in certain patients comes from India and is to be found in the Ayur Veda of Sustra. Although certain symptoms of diabetes were known to the Greek, Roman and Arabian physicians, it remained for Celsus, a Roman physician, in the latter half of the second century of the Christian era to describe its outstanding symptoms. Aretaeus, of Cappadocia, a Greek physician practicing in Rome, and a contemporary of Celsus, is said to have first used the word diabetes (*διαβήτης*, a siphon). These early accounts deal with the saccharine type.

Thomas Willis, Sidley Professor in Oxford University, in his "Pharmaceutice Rationalis" published in 1674, was the first European to describe the sweet taste of the urine, and he is credited with having differentiated a saccharine and a non-saccharine variety, but it remained for Johann Peter

Frank, in 1794, to first definitely recognize that there were two distinct forms of the disease. In one the urine possessed a honey-like taste, *diabetes mellitus*, or *verus*, in the other the urine had an insipid taste, *diabetes insipidus*, or *spurius*. Frank, first gave us a definition of diabetes insipidus, when he described it as a long-continued, abnormally increased secretion of non-saccharine urine which is not caused by a diseased condition of the kidneys. A better definition could hardly be devised for the present day.

Robert Willis, in 1838, proposed a classification of diabetes insipidus cases according to the urea excretion. *hydruria* included those cases where there was polyuria and a normal urea output, *azoturia*, those with polyuria and increased urea excretion; *anazoturia*, those with polyuria and diminished urea elimination. Subsequent experience showed that these did not represent distinct types of the disease.

From 1849, when Claude Bernard published the results of his famous piqure experiments on the medulla of animals, the investigation of the cause of diabetes insipidus entered the experimental stage. His so-called diabetic center is situated in the floor of the fourth ventricle near the tip of the calamus scriptorius and between the centers of the pneumogastric and aud-

†Presented at the Baltimore meeting of the American College of Physicians, March 26, 1931

itory nerves Puncture of this center in dogs caused a glycosuria Puncture at a point a little lower caused a polyuria, whereas punctures at a point a trifle higher in a frontal direction, he claimed, produced an albuminuria

Eckard, of Giessen, in 1870, confirmed Claude Bernard's findings and stated that there were other areas of the brain, injury of which in animals produced a transitory or permanent polyuria Kahler, writing about the same time, came to similar conclusions

In 1905, Eric Meyer advanced the view that diabetes insipidus was due to the inability of the kidneys to concentrate urine In order to dilute the serum of the blood so that the contained sodium chloride and nitrogenous products could be excreted by the kidneys, the patient was forced to drink more water, which led secondarily to an increased output of urine This theory received some support but was soon abandoned, for it was shown later by various investigators that the kidneys of patients with this disease were capable of eliminating a concentrated urine, that is, a urine with a specific gravity approaching the normal

Since 1910, there has been a very active investigation of the cause of diabetes insipidus The following three views, in succession, have been advanced

(1) That it is caused by disturbed function of the posterior lobe of the hypophysis

(2) That it is produced by organic changes involving one or more of the structures comprising the hypothalamus, and

(3) That there is a center, the *nucleus supraopticus* or *nucleus para-*

ventricularis located in the hypothalamus near the floor of the third ventricle, that presides over normal water metabolism, that nerve fibres originate in this center and pass down through the hypothalamus and infundibular stalk and spread throughout the entire posterior lobe and even between the cells of the *pars intermedia*, and that a lesion involving any part of this tract, the *tractus supraoptico-hypophyseus*, may so disturb water regulation that diabetes insipidus results

THE HYPOPHYSIS CONCEPTION

A brief review of the functions of the various parts of the hypophysis is important in a consideration of its possible relationship to the etiology of diabetes insipidus It consists essentially of the anterior lobe, the posterior lobe or *pars nervosa*, and the *pars intermedia*, an epithelial envelope which partially surrounds the posterior lobe

The anterior lobe is a glandular structure, of ectodermic origin, and derived from Rathke's pouch Its two chief functions are concerned with growth and the development of sex characteristics We are not concerned with the activity of the anterior lobe in this discussion

The true function of the *pars intermedia* still remains a debatable question

The posterior lobe is of nervous origin, and, until recently, has been thought to consist essentially of neuroglia cells and fibers The recent work concerning the histology of this lobe will be deferred for a later discussion At its upper portion it is connected with the mid-brain, or hypothalamus, by the infundibular stalk.

The chief actions attributable to the extract of the posterior lobe of the hypophysis are its pressor, diuretic-antidiuretic, oxytocic, and melanophore-expanding properties. Whether these actions are due to a single substance or to one or more different products still remains a disputed question. Abel and his associates claim to have produced all these actions from the pituitary tartrate they have isolated from the posterior lobe. On the other hand, Kamm, Grote, Rowe and Bugbee have isolated two factors, vasopressin, which exerts the pressor effect, and oxytocin, which causes contraction of smooth muscle. Gargle, Gilligan and Blumgart have shown that the antidiuretic effect is linked up with the vasopressin factor.

For several years following 1910, the theory that diabetes insipidus was dependent upon lesions of the hypophysis held sway. Only a brief reference to some of the evidence supporting this conception can be given. In 1910 Harvey Cushing, in reporting the results on the removal of the posterior lobe in dogs, found that this operation was often followed by a transitory polyuria.

In 1913 Cushing, in his Shattuck lecture, stated that in his first 100 cases of pituitary disease polyuria had been so marked in six cases that it had led to a diagnosis of diabetes insipidus by the physicians referring the patients.

The first clinical report showing a relationship between diabetes insipidus and lesions of the hypophysis was made in 1912 by E. Frank. He reported a case in a man who had been shot and x-rays revealed the fact that the bullet was lodged in the sella turcica.

In the following year, 1913, M. Simmonds reported a case of diabetes insipidus in a woman, aged thirty-seven. Two months after an excision of the breast for carcinoma she developed a marked polyuria and polydipsia. The autopsy showed, in addition to numerous other metastases, one involving and destroying the posterior lobe of the hypophysis. The metastasis pressed on the pars intermedia but did not involve it or the anterior lobe.

Following these two reports numerous similar cases soon began to appear in the literature, apparently confirming this relationship.

An additional support was given to the posterior lobe conception by the appearance of reports in 1913 by von den Velden and Farini, working independently, that the hypodermic injection of pituitrin had a marked effect in reducing the polyuria and polydipsia in this disease.

As a result of the above evidence, it was natural that the view that diabetes insipidus was due to disturbed function of the posterior hypophysial lobe should have gained rather general acceptance.

THE HYPOTHALAMIC CONCEPTION

While the hypophysial idea of the cause of diabetes insipidus was gaining ground, some experimental work appeared casting doubt on it, and indicating that the lesion was not in the posterior lobe but in the hypothalamus.

The hypothalamus, or mid-brain, forms the floor of the third ventricle. It consists essentially, from before backwards, of the optic chiasm, the tuber cinereum, and corpora mamillaria. In addition there is the infundibulum.

ulum, situated below the tuber cinereum and terminating in the infundibular stalk, which is attached to the upper surface of the posterior lobe of the hypophysis

The question of the relationship between polyuria and experimental lesions of the hypothalamus in dogs was first undertaken by Camus and Roussy in 1913. They reported that they had been able to produce transitory polyuria by puncturing the hypothalamus of dogs through the sphenoidal bone with a heated drill. In one dog a permanent polyuria, as well as a dystrophia adiposogenitalis, resulted. They believed that it was injury to the tuber cinereum that produced the polyuria.

These investigators continued their experiments, and in 1920 reported what seemed rather convincing evidence that the polyuria does not depend on a lesion of the posterior hypophysial lobe, by producing it in a dog from which the hypophysis had been previously removed. The investigations of Aschner, and of Houssay and Hug supported the findings of Camus and Roussy.

Bailey and Bremer, in 1921, reported from Cushing's Clinic a very careful piece of experimental work on dogs confirming the views of Camus and Roussy. With the technique used by the latter there was always risk of injury to the pituitary. By a special surgical technique Bailey and Bremer exposed the hypothalamus by the temporal route, which permitted an exposure of the whole region. The punctures of the hypothalamus could be made where desired, and the pituitary, being in plain view, could be carefully avoided. When the animals died or

were sacrificed sections were made of the injured hypothalamus, and of the pituitary to make sure that the latter had not been damaged in the operation. In all of their thirteen dogs in which the hypothalamic puncture was performed there developed a polyuria which appeared in the first two days. According to the extent of the lesion it varied from a transient one, lasting from six to eight days, to an apparently permanent polyuria. It is interesting to note that in some of the dogs the physical effect of the puncture on the animals resembled that following hypophysectomy. Lesions of the tuber cinereum produced in two dogs a cachexia hypophyseopriva with acute genital atrophy, and in two other dogs an insidiously developing adiposogenital dystrophy. The integrity of the pituitary was in each of these cases verified histologically. It is important to note that these researches confirmed the observations of Camus and Roussy to the effect that injury to the hypothalamus, in addition to causing polyuria, also, in some instances, resulted in the production of an adiposogenital syndrome, which has been supposed to be dependent on pituitary disturbance.

Camus and Roussy, as already stated, believed that the polyuria in experimental cases was dependent upon damage to the tuber cinereum. Richter has shown that in the rat a marked and permanent increase in water-intake and urine-output can be produced by a fine puncture made in the brain stem near the hypophysis. On the other hand Helen Bourquin produced polyuria in dogs by injuries to the corpora mammillaria.

From the clinical standpoint there was evidence that diabetes insipidus in man could be produced by hypothalamic lesions. Erdheim, of Vienna, in a publication appearing in 1904, appears to have been the first to suggest, as a result of clinical and pathological studies, that the polyurias associated with organic brain disease were actually dependent upon tumors or other lesions involving the hypothalamus. Another frequently quoted case is that of Lhermitte, published in 1922, in which diabetes insipidus developed in a case in which a syphilitic lesion involved both the tuber cinereum and infundibulum. Babonniex and Lhermitte, in 1925, reported another case of diabetes insipidus with syphilitic basilar meningitis, with lesions also involving the infundibulum and tuber cinereum. Verron reported a case following trauma, in which there was a circumscribed necrosis of the infundibulum.

In 1928 Elmer, Kedzierski and Scheps reported a case of diabetes insipidus in a patient with hypernephroma of the kidney with a metastasis in the hypothalamus. An embolus of hypernephroma cells had blocked an artery causing a necrosis of the tuber cinereum. The writer, in 1929, published the records of a case of diabetes insipidus in a man who had a primary carcinoma of the lung, with a metastasis about 1.5 cm in diameter involving the infundibulum and tuber cinereum, with an intact pituitary.

With these reported cases there seemed very conclusive evidence that diabetes insipidus could be produced clinically and experimentally by lesions involving the structures comprising the hypothalamus without any involve-

ment of the posterior hypophyseal lobe. The suspicion began to arise that when the clinical picture of diabetes insipidus occurred in growths involving the posterior lobe, as well as in the case of hypophyseal duct cysts, the cause of the polyuria and polydipsia was actually involvement of or pressure on the structures comprising the hypothalamus. In a similar way might be explained the intense thirst and polyuria that not infrequently follow the attempted surgical removal of basilar tumors in the region of the hypophysis.

THE TRACTUS SUPRAOPTICO-HYPHYSSEUS CONCEPTION

From the foregoing it will be seen that we have the hypophysis and the hypothalamus proponents of the cause of diabetes insipidus. In recent years the adherents of the hypothalamus conception have been getting rather the better of the argument. It now remains to present the evidence which tends to show that the adherents of both groups are right in their interpretation.

To clarify this point it is necessary to summarize the very important work that was published by Greving¹ and Pines² in 1926 concerning the histology of the posterior lobe of the hypophysis and of the hypothalamic region.

The posterior lobe of the hypophysis, embryologically, is of nervous origin and has until recently been supposed to be made up practically entirely of glia fibres and cells. The general impression has been that it contained no evidences of secretory cells, similar to those of the anterior lobe, which is a typical secretory gland. However, in 1927, Lewis and Lee³ showed that it actually contained groups of cells pro-

jecting inwards from the capsule, which sometimes have a tubulo-racemose arrangement in infants up to four years

The general belief has been that the posterior lobe contained no true nerve fibres or nerve cells. However, as far back as 1904, Berkley³ described and pictured nerve cells with one or more processes coming off from them. Dandy⁴, in 1913, reported on the external nerve supply of the pituitary. He found that it is derived from the carotid plexus of the sympathetic nervous system. These nerves follow the arteries supplying the various portions of the hypophysis, and he noted that very few went to the posterior lobe. No sections of the hypophysis itself were made to demonstrate whether or not nerve fibres could be demonstrated within the gland. Cajal, in 1911, was the first to demonstrate actual nerve fibres in the posterior lobe by his silver-reduction staining method. Nerve fibres in this lobe were later reported from Cushing's laboratory.

Greving¹ of Erlangen, and Pines² of Bechterew's laboratory in Leningrad, in studying the cause of diabetes insipidus, attacked the problem from the standpoint of determining whether there were any demonstrable nerve paths originating at any particular point in the hypothalamic region and communicating with the posterior lobe. Working apparently independently, they have made a contribution to this problem which appears to be of the very greatest importance. They made serial sections in an obliquely horizontal direction through the hypothalamus, hypophysial stalk and posterior lobe and stained the sections by the silver

method. Their results briefly are as follows. They find that at the nucleus supraopticus and nucleus paraventricularis, situated on each side of the median line near the floor of the third ventricle and adjacent to the optic chiasm, nerve fibres arise forming a definite bundle which passes down on each side near the tuber cinereum through the infundibulum and infundibular stalk into the posterior lobe, where they form an extensive network, and surround groups of cells which are thought to form the secretion of the pituitary lobe. Some of these fibres can also be traced between the cells of the pars intermedia. Greving calls this tract of nerve fibres beginning in the nucleus supraopticus and terminating in the posterior lobe the *tractus supraoptico-hypophyseus*. The belief is that the tract belongs to the vegetative nervous system. The tentative conception is that the nucleus supraopticus is the center that presides over the normal regulation of water balance. The fact that this center is connected by a definite bundle of fibres with the posterior lobe, the extract of which has such a potent effect in relieving the polyuria of many cases of diabetes insipidus seems to be of the greatest significance. Cushing, in his Lister lecture of 1930 emphasizes the importance of the work of Greving and Pines, and seems to accept the view that there is a water regulatory center, the nucleus supraopticus. In referring to the work of these investigators he says, "When successfully stained, however non-myelinated nerve fibres in abundance at first can be traced from both the supraoptic and paraventricular nuclei (though more particularly from the

former) to converge at the infundibulum, whence in a compact bundle they pass down the pituitary stalk to enter the posterior lobe. Arrived there, they not only ramify widely throughout the pars nervosa weaving themselves as Greving states, in 'basket-like' fashion around what appear to be secretory islands, but they also, according to Pines, can be traced in among the epithelial cells of the pars intermedia."

The existence of this tractus supraoptico-hypophyseus, as described particularly by Greving, renders it probable that diabetes insipidus may result from lesions anywhere along its course, as suggested by Zadek.⁷ What relation this tract has with the cause of dystrophia adiposogenitalis has not been definitely settled. Greving suggests strongly such an association. Clinically, we not infrequently find a combination of diabetes insipidus and adiposogenital dystrophy. In the polyuria produced experimentally in animals, both Camus and Roussy, and Bailey and Bremer reported that in some instances the animals manifested both diabetes insipidus and also dystrophia adiposogenitalis. It is probable that the tractus supraoptico-hypophyseus was severed in these experiments. That a disturbance in the continuity of this tract may produce both conditions was reported by Cushing in his Cameron Lectures in 1925. He and Maddox, by placing a silver clip on the hypophysial stalk of dogs, after shrinking the brain by Weed's method so as to prevent damage to the mid-brain and hypophysis, produced both polyuria and dystrophia adiposogenitalis in the animal.

The discovery of the tractus supraoptico-hypophyseus goes a long way

towards reconciling the conflicting views of the pituitary and hypothalamic adherents. We can conjecture that it may be found that tumors or other lesions involving the nucleus supraopticus, the posterior lobe of the hypophysis, or of the tract anywhere between these points may produce diabetes insipidus.

TREATMENT

Only a brief reference to the treatment of diabetes insipidus can be made. If the patient has a positive Wassermann antiluetic treatment should be instituted, as the polyuria might be dependent upon a gumma of the mid-brain or upon a basilar syphilitic meningitis.

Surgical interference is often indicated where there are neighborhood pressure symptoms, such as headaches, ocular palsies, bitemporal hemianopsia, and choked discs. An early operation may prevent total blindness, even though it may not materially influence the polyuria.

The hypodermic use of 0.5 to 1 cc of surgical pituitrin often relieves the distressing thirst and polyuria. The dosage and interval between doses has to be worked out in each individual case. Usually the effect of an individual dose does not last longer than from four to six hours. Following basilar tumor operations, a distressing diabetes insipidus may develop when it did not previously exist. Frequently this polyuria and polydipsia will spontaneously disappear. If it does not, pituitrin therapy is indicated. The cause of the diabetes insipidus in these cases is probably due to damage to the supraoptico-hypophyseus tract during the operation.

Blumgart has found that the nasal administration of pituitrin is sometimes effective. A tampon of cotton soaked with pituitrin may be inserted into one nostril, or 1 cc of pituitrin may be diluted with 30 cc of normal salt solution and frequently sprayed into the nostrils.

In some instances it is found that pituitrin has little or no effect. Elmer, Kedzierski and Scheps⁸ have proposed a classification of diabetes insipidus from an etiological and therapeutic standpoint. It is as follows:

(a) Cases due to destruction of the posterior lobe of the hypophysis. Here the posterior lobe extract fails entirely or only in part to sensitize the regulating centers for water and salt in the hypothalamus. In these cases pituitrin has a definite, though transitory therapeutic effect, because the regulatory centers in the hypothalamus are intact.

(b) Cases due to destruction of the water and salt-regulatory centers in the hypothalamus. In these the secretion of the posterior lobe is still produced, but it cannot sensitize the hypothalamic centers because they are destroyed. In this group the pituitrin has no effect whatever, since the regulatory centers in the hypothalamus are destroyed and are incapable of sensitization.

(c) Cases in which there is an interruption of the communicating nerve fibres connecting the hypothalamus (tuber cinereum) and the posterior lobe of the hypophysis. This group, they state, is insufficiently understood and requires further investigation. The therapeutic effect of pituitrin is not stated.

If the views of these authors be correct, the failure of pituitrin to act therapeutically may be referred to those cases where the so-called center or centers are destroyed.

the burden represented by the weight loss. With very few exceptions, also, hunger disappeared within several days. When they found they could lose thus rapidly without hunger and with a feeling of increased energy, instead of lassitude, they were encouraged to continue and this contributed to the ultimate success obtained in these patients. The probable reason for these fortunate symptoms presents another contraindication to the use of thyroid in the treatment of obesity.

Patients on this dietary régime showed a more rapid reduction in the calories per hour oxygen exchange than in weight.⁷ The calories per hour of the patient presented above fell from 69 to 53, converting the basal metabolic rate calculated on her ideal weight from plus 25 at the beginning to minus 3 at the end of the dietary period. This is sufficient explanation for the increased resistance to fatigue and feeling of well-being these patients reported.

DuBois⁸, and Strang and McCluggage⁹ have shown that the rise in calories in response to a fixed meal—the specific dynamic action of the meal—is quantitatively the same in the obese and those of ideal weight if they are otherwise normal. Strang and McCluggage⁹ also presented evidence that the feeling of satiation after food comes from the attainment of the optimum rate of change of metabolism in response to it. With a fixed specific dynamic action this rate of change of metabolism is of course less in relation to a high basal metabolism than to a low one. In other words, it takes more food to give a feeling of satiation in a person with a high basal metabolic

rate than in one with a lower one, or conversely, the satiation from a fixed amount of food is greater with a low basal metabolic rate than with a higher. These observations related to the lowering of the basal rate of oxygen exchange observed in these patients probably accounts in part at least for their feeling of contentment with the food given.

If the drop of basal calories per hour oxygen exchange in these patients were prevented by thyroid medication, two worthwhile results now obtained probably would not occur. They would not have the increased resistance to fatigue and their appetites would not be as satisfied with the food given. They would, therefore, not feel so encouraged to continue and the ultimate results would probably not be as good.

THYROID MEDICATION INDICATED

While the 187 patients so far discussed were being successfully treated as described, four patients were found to whom thyroid administration was thought desirable because of a slow rate of weight loss. One woman who weighed 259 pounds was first seen after three months in bed because of another disability. Her calories per hour were 59, giving a basal metabolic rate of minus 26 for her actual weight and minus 8 for her ideal weight. After four weeks of dieting the calories per hour were 54, giving a basal rate for her actual weight of minus 34 and minus 18 for her ideal weight. The other three were young women in whom initial basal metabolic rates within normal limits early in the dieting period fell to levels somewhat

below that normal for their ideal weight. They all reacted well under thyroid therapy combined with the diet, but so controlled that caloric exchanges never higher than normal for their ideal weights were obtained. No doubt each one of these patients had hypothyroid tendencies, but if they did there was no demonstrable clinical evidence of it. This observation is important in showing that there is no clinical evidence other than the basal metabolic rate by which the very rare patient in whom thyroid medication may be used to advantage can be picked out from the large group in which it is contraindicated. In these its use should be controlled by frequent basal metabolic rate determinations because if pushed to high levels the same undesired results as those discussed above for the patients in whom its use is contraindicated would, no doubt, ensue.

CONCLUSIONS

I. Thyroid administration in the treatment of most cases of obesity is not necessary because

1. A diet consisting of one gram of protein and three-fifths of a gram of carbohydrate per kilogram of ideal weight, and no more than fifteen to twenty grams of fat, gives diets of from four hundred to six hundred calories on which these patients come down rapidly without thyroid

2. They may be maintained on these diets for months if necessary with nothing but improvement in their general condition.

II. Thyroid administration in the treatment of most cases of obesity is contraindicated because

1. The calories per hour oxygen exchange giving a normal basal metabolic rate when calculated on the actual weight, if related to the ideal weight, give a figure considerably higher than normal. This represents one of the physiological strains of obesity which should not be increased by thyroid therapy.

2. The drop in the basal metabolic rates with the institution of limited diets probably accounts for the feeling of well-being and increased resistance to fatigue observed by these patients and in part for the feeling of satiation with the lowered food intake which affords contentment with the diet prescribed. This encourages these patients to persist and should not be eliminated by thyroid medication.

III. A few patients—perhaps no more than two per cent of all—do not lose weight rapidly without thyroid medication. These cannot be differentiated from the others by history or physical findings. They may be recognized with assurance only by repeated basal metabolic determinations during the course of dieting.

The Many Sided Question of Protein In Nephritis*†

By W S McCANN, M D, F A C P, *Rochester, N Y*

IN THE practical management of patients with nephritis, regardless of the type, the question of the protein metabolism assumes a position of great importance. When one considers the varied rôles played by proteins in the body, the problem of controlling or modifying their behavior becomes one of great complexity. The catabolism of protein, giving rise to urea, sulphuric and phosphoric acids, must be limited to the capacities of damaged kidneys to excrete these substances. The anabolic demands for protein must not be overlooked, as physicians have been prone to do, because new protein synthesis is often urgently needed to replace that destroyed by "wear and tear" or lost during albuminuria, and to regenerate dwindling serum proteins which have come to play such an important part in the maintenance of the water balance of the body. So prevalent has been the idea that protein catabolism exerts deleterious effects upon the kidneys and vascular system that patients are seen not infrequently with "hunger edema" due to protein

starvation resulting from the severe and prolonged restriction of the protein of the diet, and states of less marked malnutrition from this cause are common. Physicians fall into the error of assuming that the sole means of reducing the catabolism of protein is that of reducing its intake, forgetting that the endogenous metabolism may remain high even though little protein is taken in the diet. It is important, therefore, that attention be called to other methods for reducing the catabolism of protein and of increasing its deposition in the body for the replacement of body proteins destroyed by the "wear and tear" of living in health or in disease, as well as protein lost during albuminuria.

The catabolism of protein in the nephritic patient is influenced by the same factors which operate in most other individuals. There is the so-called "wear and tear quota", which is heightened by "toxic destruction" in the presence of fevers of infectious origin such as those which frequently precede or accompany hemorrhagic nephritis. Furthermore, when the supplies of fat and carbohydrate are inadequate protein catabolism is increased, so that we say that fats and carbohydrates spare protein. Finally we have to consider what happens when a man consumes more protein than is

required to cover the irreducible minimum of wear and tear on body proteins

A normal man, provided he were physically capable of ingesting an amount of protein sufficient to cover his energy requirement for rest in bed, would experience an acceleration of his total metabolism as the result of such ingestion so that 40 per cent more heat would be produced in his body than the food protein could furnish. The energy for this extra heat would be derived from his stores of carbohydrate and fat. Rubner and Lusk¹ have called this the "specific dynamic action" of protein. A normal man, fully grown, will quickly adjust the level of protein destruction to protein intake, so that he is in nitrogen balance, provided the total energy of the food is adequate. If he does what Sívén² did, namely, reduces his protein intake to lower and lower levels, his urinary nitrogen excretion will fall to a minimal level of 3 to 4 gm per diem at which nitrogen balance can be established. In order to do this he must consume proteins of high "biological quality" in the sense of Thomas³, that is, proteins which contain all the necessary amino-acids required for the synthesis of human body proteins. Larger amounts are required if the proteins consumed are deficient in this respect, as many of the vegetable proteins are.

If our previously normal man were to acquire typhoid fever or a streptococcal infection, nitrogen balance could no longer be established at a low level, or, in fact at a high level, unless the total caloric intake were raised to many times the resting energy requirement

as the work of Shaffer and Coleman has shown⁴. The difference between these two levels at which nitrogen balance could be established is the measure of the "toxic destruction of protein". Even in tuberculosis, which causes only a slight toxic destruction, the writer⁵ found that the minimal level of nitrogen balance could be reached only when the patients were able to take from two to two and one half times the number of calories required by the patient for rest in bed.

When toxic destruction ceases and convalescence begins the wasted body seizes upon food protein with avidity and replaces that destroyed, so that nitrogen excretion may remain low even when the intake is high. The same phenomenon follows periods of partial or complete starvation. Let us apply some of these considerations to the case of a young man with acute hemorrhagic nephritis. During the attack of scarlet fever or of tonsillitis which preceded or ushered in the nephritis, toxic destruction of protein occurred and will persist as long as the infection lasts. During this period increased amounts of the end products of protein catabolism will be produced no matter how low we reduce the protein intake. As water excretion is reduced these end products are retained and usually appear in increased amounts in the blood of such patients. If we reduce the salt intake and administer water the urine volume may increase to an amount adequate to sweep the blood clear of extra urea. In such cases it is usually possible to increase the intake of carbohydrates to a high level and in this way to dimin-

ish to some extent the abnormally high endogenous metabolism of protein

Edema will probably have occurred at first without low serum proteins. The urine will show increased amounts of serum albumin and serum globulin, fibrinogen, and hemoglobin, representing considerable losses to the body which should ultimately be replaced. The urinary globulin and the hematuria, as Van Slyke and coworkers have shown⁶, give us a fair measure of the intensity of the damage to the kidney. Prolonged loss of these substances diminishes their amount in the blood, producing anemia and reducing serum proteins. Years ago Starling⁷ showed that the balance between the osmotic pressure of the serum proteins and the hydrostatic pressure in the capillaries determines the escape and return of water to them. With the reduction of serum proteins the edema of our patient will tend to increase, particularly if the reduction affects chiefly the albumin fraction, which has a much greater swelling pressure than the globulin.

Experience has taught us that many cases similar to this one will undergo a transition along the following lines. The hematuria and urinary globulin will diminish greatly as the intensity of glomerular damage abates. Albuminuria and edema may increase until a clinical picture results which may closely simulate that of a primary degenerative nephritis or nephrosis, in which the predominating lesion is tubular degeneration. We have a suggestion as to how this comes about from the experiments of two of the younger workers in Christian's clinic. Barker and Kirk⁸, who depleted the serum

proteins of dogs by plasmapheresis and found that if this were continued tubular degeneration ensued.

Various workers have studied the regeneration of serum proteins after plasmapheresis. Kerr, Hurwitz and Whipple⁹, found that the regeneration period was shortest on a meat diet, longer on bread and milk, and longest during fasting, and that it was much prolonged when the liver was injured by chloroform or excluded by Eck fistula. Epstein¹⁰ sought to build up the serum proteins in nephrosis by giving high protein diets with considerable success. The writer, in unpublished experiments, has observed the effects of similar high protein diets on edematous patients with chronic hemorrhagic nephritis, the results of which may be summarized here. The patients invariably retained nitrogen, presumably as deposit protein, since non-protein nitrogen of the body fluids did not increase. Only a small fraction of the deposited protein appeared as circulating protein of the blood serum. The major portion of the deposit being outside the vascular system increased the water held in the tissues so that the weight increased and edema increased until the slowly increasing serum proteins reached the point at which increased diuresis and loss of edema could occur.

Before applying these results to other patients with hemorrhagic nephritis we should satisfy ourselves that the increase of protein in the ration will have no deleterious effects produced by disturbing the mechanism for acid-base balance or by possible renal damage by protein which the work of Newburgh¹¹ and others suggest.

For the maintenance of the acid-base balance the kidneys play a most important part. The non-volatile sulphuric and phosphoric acids resulting from protein catabolism are excreted largely by the kidneys, though partly through the bowel. When these acids pass through the kidneys normally *ammonia is formed by the kidneys* to accompany them, as shown by the work of Nash and Benedict¹¹. This normal ammonia formation prevents the loss of fixed bases and protects the alkaline reserve of the blood. In nephritis the mechanism fails in two ways. Retention of these non-volatile acids reduces the CO₂ combining power of the alkaline reserve. The ammonia forming function is frequently impaired in hemorrhagic nephritis. Observations made by Palmer and Henderson¹² in 1915 show clearly the reduced urinary ammonia of patients with renal acidosis. The failure of this function results in a drain upon the reserves of fixed bases which must accompany acids excreted in the urine, in the absence of adequate ammonia formation.

In the presence of renal damage sufficient to limit acid excretion or ammonia formation, an increase of protein in the diet is justifiable only when the catabolic processes can be limited and the anabolic augmented. Protein deposited makes no demand on the excretory mechanism or on the regulation of acid-base balance. Protein destroyed does make a great demand, but within limits this may be compensated for by increasing the basic constituents of the diet derived from fruits and vegetables or administered as the alkali-salts of citric or other organic acids. The problem of renal acidosis

presents a difficulty which is not insuperable.

Newburgh¹³ has raised an important question as to the possibilities of producing renal injury by protein in the diet. He was able to produce renal lesions in white rats, by feeding them diets consisting of as much as 75 per cent dried liver, casein, or beef muscle. Such liver feeding produced granular kidneys in less than a year. Casein produced tubular injury in 16 months, while beef muscle produced changes intermediate between the two. Looking at these results critically one is struck by the fact that a far greater proportion of protein was given to the rats than could possibly be taken by man, and also by the probability that the differences between the effects of the materials fed may depend upon substances associated with the simple proteins, possibly substances arising from nuclear material. Dr Newburgh has kindly permitted me to mention that further experiments of his, which will soon be published, indicate that the latter supposition is probably true. Substances like liver may produce renal injury if taken long enough and in sufficient amount. It remains to be shown that such injury occurs in man in the amounts which can ordinarily be taken.

On the other hand, we have the testimony of Stefansson as to the absence of injurious effects in the case of the Eskimo who gets 40 per cent of his energy from protein. McClellan and DuBois¹⁴, who recently completed a year of observation of Stefansson and Anderson on a meat-fat diet such as one may live on in the Arctic regions, found no demonstrable injury of

any kind Also McCay¹⁵ of the Indian Medical Service has testified that the incidence of nephritis is no greater among the meat eating Europeans in India than among the Bengali who get very little good protein

In the writer's clinic, Dr Henry Keutmann has carried out some very careful observations of the effect of high protein in the diet on the course of chronic hemorrhagic nephritis These observations are being published in detail elsewhere Patients were selected who had come to a fairly constant level of hematuria as measured by the Addis sediment counts¹⁶ In the following table are compared some of the observations made in a typical case of a boy of 15 years with chronic hematuria following upon an attack of acute nephritis, months before Comparison is made between the findings during two weeks on a diet containing 75 gm protein and during four weeks on a diet containing 150 gm

During the experiment the patient improved clinically, showed no elevation of blood pressure, maintained con-

stant weight and a positive nitrogen balance The relationship between the urinary ammonia and the total titratable acidity remained unchanged though both of these were increased 50 per cent when the protein intake was doubled

SUMMARY

These experiments have convinced us that liberal protein allowances in the diet do not of themselves, injure the kidneys When the excretory power is nearly at the level of the minimal endogenous protein catabolism which can be achieved by making full use of the protein sparing qualities of carbohydrate and fat, nothing is gained by reducing the protein intake below the point of nitrogen balance Full advantage should be taken of the tendency to deposit protein by all individuals who have lost it, either by inanition or by toxic destruction or through albuminuria Protein which is deposited makes no demand upon excretory functions, it builds up depleted tissue and circulating proteins with beneficial effects upon the course of the disease

Mountain Fever and Spotted Fever of the Rocky Mountains—Clinical Studies*

By NOXON TOOMEY, B A , M D , F A C P , *Palmira, Mo*

UNKNOWN fevers first encountered by white immigrants in the Rocky Mountain region between 1850 and 1873 have become of constantly increasing clinical interest and public health moment due to recent discoveries of new and widened endemic areas, and to the involved medical problems now more fully appreciated.

Scientific study of fevers in the Rocky Mountain region began clinically in 1880, epidemiologically and pathologically in 1902, bacteriologically in 1906, immunologically in 1908, and preventively in 1911. These studies have so increased rather than narrowed the fields of inquiry that much of what has been written has had to be rewritten from time to time to accommodate the newer scientific facts and observations relative to the spread and increasing knowledge of this disease or these diseases. So great has been the enlargement of the public health and scientific relations of spotted fever and its congeners within the last four or five years that standard monographs of a few years ago give a very inadequate picture of the economic and medical problems as now known. Hence a comprehensive clinical study taking into account the newest sci-

tific facts can further perfect the literature of internal medicine.

Of the group of mountain fevers in the western part of the United States we will first consider the component of the group that is now the best known, namely spotted fever, although there is reason to believe that the non-exanthematous, intermittent tick-borne disease (mountain fever) was encountered by white men equally early or earlier than spotted fever. The early history of the intermittent or mountain fever is more obscure because, being non-exanthematous, it was more difficult to unequivocally distinguish it from the other prevailing fevers of the mountains such as malaria and the fevers of the enteroida group.

EARLY HISTORY OF SPOTTED FEVER

Occurring among the Shoshones, Flatheads and Nez Perce Indians of southern Idaho, western Montana, western Wyoming, northeastern Nevada, and northwestern Colorado prior to immigration by Caucasians, *spotted fever of the Rocky Mountains* first occasioned illness among white settlers in 1873. It was first observed by Dr H. Dressing near Paradise Valley, Humboldt County, Nevada in 1882 and five years later by Dr. Conaghan.

*Submitted for publication July 31, 1931.

of Corvallis, Montana In the same year, 1885, it was observed in Lake County, Colorado, and in 1886 in Mesa County, Colorado It has, however, only recently attracted notice in those counties although it has apparently occurred there from time to time¹⁶⁴.

Although at first variously diagnosed as 'black measles', cerebrospinal fever, dengue or typhus, from 1880 to 1895 it became apparent to the more observant physicians practicing in the heavily infested areas that they were confronted with an undescribed disease or group of diseases At that time a modicum of the local practitioners considered mountain fever as distinct from spotted fever, but as the former term was used more loosely than the latter it undoubtedly included some other fevers seen at high altitudes And yet despite admitted unskilled diagnoses and recognized looseness in the use of the term mountain fever, the idea persisted in the minds of some judicious observers that there was a mountain fever that was not spotted fever, malaria, nor typhoid fever That fever they considered to be very probably an independent infection

The prevailing idea of local medical opinion in Idaho, reached prior to 1893, became known to Captain Marshall W Wood, U. S. A., Post Surgeon of Boise Barracks, Idaho, who reported the current opinion to the Surgeon-General of the Army. On the latter's direction Capt Wood later obtained brief clinical descriptions of the spotted disease from eight general practitioners These reports were published in 1896 under the title "Spotted Fever

The first public discussion of spotted fever and mountain fever was by the Idaho State Medical Society at Boise, Idaho, in 1896 (discussion opened by Dr William C. Maxey), and by the Rocky Mountain Interstate Medical Association at Salt Lake City in July, 1897 Neither meeting gave rise to published accounts of the discussions⁴⁶

Clinical studies made by the Maxeys, father and son, and reported by the son, Dr Edward E. Maxey, characterized the main symptomatology of the indigenous spotted fever and served to emphasize that in southern Idaho the disease was more prevalent but not nearly so virulent as in western Montana²

Satisfied of the infectious nature of the new and imperfectly studied disease, the first act of the newly organized Montana State Board of Health was in 1901 when it commissioned L. B. Wilson and Wm. M. Chowning to make an epidemiological and pathological study of the indigenous disease, with particular reference to the virulent form in the Bitter Root Valley Wilson and Chowning in their reports remarked upon mild, febrile cases without an eruption and of unknown nature, but did not make a study of cases of the sort, nor express an opinion as to their nature⁸

The chief permanent results of Wilson's and Chowning's studies were to make the Bitter Root Valley form of spotted fever more widely known, more fully described clinically, and more scientifically established in that their epidemiological studies led them to focus attention on ticks as vectors of the disease, without, however, actually establishing the fact They described

a piroplasm which they thought they saw in the blood of patients with the virulent form of the spotted fever, and attached etiological significance to it. Later, however, C W Stiles and W W Welsh recognized these supposed intra-erythrocytic organisms as artefacts¹⁵

Wilson and Chowning's supposition in regard to a tick as vector of the spotted disease was confirmed experimentally by McCalla and Brereton who in 1905 transmitted the mild, Idaho type of spotted fever to man (two cases) and by King and Ricketts who transmitted the virulent Bitter Root Valley strain of the disease to guinea-pigs by means of tick attachment (feeding) experiments

The high mortality rate (70 to 90 per cent) and the economic importance of the malignant Bitter Root Valley form of spotted fever so centered the attention of investigators on it that the benign, aberrant and non-exanthematic forms of local fever attracted almost no scientific study, with practically the sole exception of the mild form of spotted fever indigenous to the Snake River Valley in Idaho, which on account of its habitual low mortality rate (5 per cent) had from the earlier days led some to consider that it should be recognized as a separate disease. However, by means of later serologic studies the Idaho form of the disease has been proven to be immunologically identical with the malignant Bitter Root Valley form although amply warranting consideration as a distinct and easily recognizable clinical type due almost certainly to a fixed difference in the virulence of the local strain of the virus

As an historical account of the laboratory, and other scientific work done on these fevers since Ricketts first took up the problem in 1906, would have to do exclusively with the exanthematic or spotted fevers peculiar to the Rocky Mountain area, an account of the discoveries connected with them will be deferred until after presenting a discussion of mountain fever

MOUNTAIN FEVER

Dismissing the fact that the term mountain fever has been used in almost all languages for whatever zymotic distemper may have prevailed at the time in the high altitudes of the region, it will for our purpose be sufficient to note that the fever under discussion is not implied to have any relationship with the mountain fevers of Europe, India, or any other part of the globe and is used only with respect to the medley of febrile diseases that have laid men low in the Rocky Mountain areas

As a popular sobriquet for plasmodium infection, *Eberthella typhi* infection, or one of the paratyphoid fevers (including tularemia and brucellosis), the term mountain fever has perhaps enjoyed most currency in the mountainous West. Connoting nothing to the medical mind, the use of such a term in medical literature is usually regarded as a token of ignorance. Nevertheless the term has a history and a persistency in the West and it is for us to determine if possible whether by it a separate disease entity has at times been designated

The earliest professional use in the West of the term mountain fever had to do largely with remittent and inter-

mittent fevers although by some the term was used for the continued fevers, including no doubt tularemia and abortive and masked forms of typhoid fever³. Although these reports were grouped by eastern bibliographers and clinicians with the aberrant forms of typhoid fever, the remittent and intermittent character of some of these mountain fevers stands out clearly. Also one is impressed by their comparatively *short duration* (eight to fourteen days), the *seasonal incidence* (April to June), the relation of *protracted chilliness but no chill* to fever, and the admitted *lack of effect of quinine* on them¹³. Furthermore, we know today that in some of the high mountain passes and valleys from which the "brief intermittent fever" was reported, plasmodium infection *must have been absent* in the early days as the necessary vector, an anopheline mosquito, *was not indigenous above the valleys of the plains*.

As in these cases no skin eruption was reported it would not conform to our present conception of spotted fever to regard them as being one and the same disease, nor cerebrospinal fever. That a focal infection (streptococcal or pyogenic), or bronchopulmonary invasion would explain all cases not due to a plasmodium or an enterococci, would seem most likely, and certainly some cases of tularemia would be confused with the doubtful group. Dengue or influenza perhaps accounted for the "epidemic mountain fever" mentioned by E. P. Vollum, and yet neither of these are apparently the endemic, seasonal, "brief remittents, easily cured" of the north Rocky Mountain region. A brucellosis (undulant fever) might

be the explanation of the mountain fevers of uncertain origin but if so it is extremely difficult to account for army cases being referred to as brief, for brief they must have been, because it is well known that in the army not only are men able to consult a doctor on the slightest pretext but do so to escape doing duty, hence it is unlikely that any of these army cases much exceeded two weeks, whereas brucellosis usually runs not under two to four months and usually longer; such a long protracted, low, ambulant fever would become known to the army medical officers in the West, and would have been described as such and not as "brief remittents easily cured". Furthermore we now know that mountain fever is tick borne and not milk borne, and is seasonal whereas brucellosis is not.

As for bronchopulmonary invasions accounting for these fevers of debatable nature we need have little concern as bronchitis, pleurisy and pneumonia in high altitudes are clear cut, particularly severe, diseases with localizing thoracic symptoms and signs so intense as not to escape the attention of a physician. It is therefore chiefly atypical plasmodial fevers, the focal infections and the zymotic infections of influenzal type that might give currency to an idea of mountain fever as being something apart from the previously recognized types of intermittent or remittent fever.

From none of the early literature on mountain fever in the West, after excluding cases of presumable plasmodium infection or the enterococci, can anything indisputably defensible from the standpoint of individuality be ex-

tracted, as the focal infections or the zymotic infections of influenzal type can perhaps be invoked to explain the cause of the remaining undefinable cases. And yet through the maze of numerous early but unsatisfactory descriptions of non-exanthematic febrile cases in the Rocky Mountains, one catches glimpses of a brief remittent fever that does not conform to known forms of paludism, the fevers of focal origin, or influenzal attacks of gastrointestinal or upper respiratory tract type. This fever, after years of comparative study, was eventually characterized as follows: as being seasonal (limited to the spring and early summer months), as being of brief total duration with one to three forty-eight hour remissions with intermissions of two to eight days duration, with pronounced, prolonged chilliness at onset (which was fairly sudden) but without rigor, as being accompanied by constipation and severe muscle aches and pains (chiefly in the back and loins, with headache occasionally) and followed by a quick convalescence but a terminal anemia. Nothing was said about a skin eruption.

Mountain fever was observed to occur only in the spring and early summer months (tick season) and was categorically stated to be different from the autumn and winter fevers. It certainly was what the early practitioners in the mountainous portions of the West had in mind when they refused to ascribe to the eastern dictum that all mountain fevers were either malaria, typhoid fever, rheumatism (focal infections), cerebrospinal fever or influenza. As to the etiology and epidemiology of mountain fever nothing

was predicated, certainly ticks as vectors of the disease were not so much as suspected, although now known to be at least one of the vectors.

Due to limitations of space, only two extracts from the early literature will be given verbatim. One is an instructive tabulation of case incidence of mountain fever.¹¹ Despite the medley of fevers that were confused under the name 'mountain fever' the incidence of cases paralleling the tick season strongly suggests the occurrence of a special tick-borne disease. The second quotation is typical of many reports from army surgeons on duty at Wyoming, Montana and Utah military posts in the early days. This quotation is from the surgeon of a cavalry command of about five hundred men who were, in 1878, marched through the Wind River Canyon of Wyoming, one of the celebrated mountain fever and spotted fever areas of early as well as recent years. Although one man died of typhoid fever verified by necropsy, the bulk of the cases were acquired over a sixteen day period (four day bivouac and twelve day march through the mountains) at the end of which all were so nearly well as not to require hospitalization on reaching Fort Fetterman. Of these cases Doctor Gray wrote:

'These cases all presented the same general phenomena in the beginning. Invariably the first complaint was that of achine, cold and 'aching all over'. Then there was loss of appetite, thickly coated tongue and constipated bowels. The disease was in all instances ushered in with a well marked chill and during the first twenty-four hours the fever was always light. But there was mental obscurity, sometimes delirium, more or less during the subject's recovery. To care whether they lived or died was

was done with or for them. The patient always admitted a feeling of distress, but never could localize it, except in one case (the man who subsequently died at Fort Fetterman, who complained greatly of pain in his head and the 'back of his neck'). The fever once developed, never after wholly left the patient, but exhibited a decided daily exacerbation, beginning with *chilliness* for a period of half an hour or so, accompanied by cold, clammy sweat, and followed by an intensely hot skin, with small and rapid pulse. These exacerbations generally continued about eight hours, sometimes longer, and then would follow a period of eight or ten hours of lower temperature and comparative freedom from discomfort, during which sleep was possible. There was an increasing, but not a great degree of prostration, as every man was able to ride his horse during the day's march of eighteen to twenty-five miles, and continued to do so daily without assistance until Fort Fetterman was reached. There were wanting the distinctive symptoms characteristic of typhoid, and yet quinia seemed to have no effect to prevent or control the daily return of the high fever, though administered in large doses."¹³

For a most valuable early account of mountain fever we have the report of Captain Charles Smart who strenuously tried to make mountain fever out to be malaria. By his own admission he had to write from Fort Bridger, Wyoming:

'I could not bring myself to record these cases as malarial remittents but put them down as catarrhs and quincies, and awaited developments. These came in a very short time. Cases appeared of fever without any complication by local lesion, and I recognized that I must be dealing with the incipency of our so-called mountain fever.'

He concludes a most careful description of three seasons' (Springs of 1874, 1875, 1876) experience with the ac-exanthematous, intermittent, tick-borne mountain fever, as follows:

"One point, however, remains to be mentioned. It is that the records of the post, the figures left behind them by my predecessors as embodying their experience of the prevalence of mountain fever, corroborate my own observation, showing the months of May, June, and July to be the months of visitation. Thus, during the eight years previous to my assignment, May gave an average of 560 cases per thousand of mean strength, June, 1389, and July, 947, while no cases were recorded during the months of September and October. Yet Dr. Drake reports those very months of September and October as the period of maximum prevalence of malarial fevers in the United States.

The following table shows the average strength of the command and the prevalence of this fever in cases per thousand of mean strength —

Month	Strength	Cases
January	172	436
February	167	75
March	169	149
April	154	162
May	134	560
June	135	1389
July	132	947
August	145	426
September	131	
October	156	
November	171	585
December	168	74
Annual	153	4803

The same author writing of Camp Douglas, Salt Lake City, mentions three cases which "after being discharged from hospital as entirely recovered, made his [their] appearance in eight days with a recurrence of the febrile attack, but it was readily removed by quinia and no subsequent relapse has taken place."

The first account of the non-exanthematous, intermittent tick-borne (mountain) fever that has come to my notice is the following which was writ-

ten by Assistant Surgeon Patzki at Fort Steele, Wyoming Territory, in 1875, and is as follows

"A remittent fever, occasionally very severe, is met with, by the mountaineers called mountain fever, and much dreaded by them. The most prominent symptoms are headache, severe aching through the whole body, insomnia, furred tongue, frequent full pulse, constipation. Chills are infrequent. The efficacy of large doses of quinine proves the malarial origin. The mountaineers treat it with their panacea, sage tea, and, as they assert, quite successfully. Men cutting timber along the streams, mostly Danes and Swedes, suffer most from this fever."¹⁰

Before considering the modern writings on the subject of mountain fever we will review the scientific work done on its 'family relation', or perhaps congener, spotted fever of the Rocky Mountains

THE RECENT HISTORY OF SPOTTED FEVER

From 1906 to 1911 the scientific work of H. T. Ricketts, P. G. Heine-
mann, and associates contributed greatly to a knowledge of the virus, the factors of transmission, the immunological reactions and the morbid anatomy of spotted fever. Later, in 1918, Wolbach added pathological and bacteriologic data and advanced as the causal virus a minute organism, a rickettsia which he was unable to cultivate except in tissue cultures.¹⁴⁶ Noguchi in 1923 was unable to confirm Wolbach's work but did show that three strains of rickettsia were non-pathogenic and that a filterable virus could be obtained from the vector, *Demacantor andersoni*. Ricketts and Spencer and Parker were not successful in forcing the virus through a Berkefeld filter.²⁰¹

For our present purpose it is more important to note the tick control measures instituted by McClintock and Bishopp and augmented by Fricks, the tick parasites introduced and propagated in Montana by R. A. Cooley²⁰⁷, who has contributed valuable ecological studies of tick biology and distribution⁸⁶, the accurate statistics of spotted fever maintained by Dr. W. F. Cogswell, secretary of the Board of Health of Montana, and the epidemiological and parasitologic work of R. R. Spencer and R. R. Parker called forth by the spread of the disease since 1914.^{108, 114, 129} F. L. Kelly⁹⁸, J. G. Cumming¹⁰⁹, F. C. Stricker¹³¹, A. B. Tonkin²¹⁴ and particularly F. E. Becker^{161, 203} have studied spotted fever in its now more widely extended endemic area.

Lately (1931) Rumreich, Dyer and Badger have discovered an eastern and southeastern states endemic area that is believed to have been in existence for at least the past twenty years.²¹⁹

Spencer and Parker have introduced a practical vaccine of great preventive value.²⁰¹ Since 1925 between twenty to twenty-five thousand persons have been vaccinated with it.

Although the above mentioned studies were undertaken without reference to the non-exanthematic intermittent tick-borne (mountain) fever they constitute an invaluable foundation for future work on mountain fever.

MODERN OBSERVATIONS ON THE INTERMITTENT NON-EXANTHEMATIC TICK-BORNE (MOUNTAIN) FEVER

In 1896 from Fort Washburn, Wyoming Henry I. Ravenel described as typhoid fever a peculiar

of Rocky Mountain spotted fever and also non-exanthematic cases of two to four day fever with one remission lasting two or three days after an intermission of two or three days, and a short 6 to 8 day) total duration²⁹¹ Raymond was apparently unfamiliar with the medical ideas prevailing in Idaho and Montana with respect to spotted fever. His cases were all observed in the tick-season (late April to June) but as he finally regarded his cases as typhoid fever he incriminated the water supply and did not look for an insect vector. His case reports (Cases W S, J P, J F S, J C, F G W, and D A) leave no doubt that he observed cases of the intermittent, non-exanthematic tick-borne disease later described by Kieffer from a point in Wyoming some two hundred and fifty miles south-eastward. Raymond remarks on the prevailing divergence of opinion among the local practitioners, one of whom (Dr H L Callaway) clearly distinguished his typhoid fever cases from the spotted fever cases, which were then diagnosed as purpura simplex and purpura rheumatica (simplex).

In 1901 Dr W W Woodring of Mt Pleasant, Utah, before the Rocky Mountain Interstate Medical Association maintained "that there is such a thing as mountain fever, mostly confined to the young and those under fifty. It is ushered in with a chill followed by a temperature of one to four degrees during the following twenty-four hours." ¹ (Quoted from abstract in Jr Am Med Assoc.)

In 1902 Wilson and Chowning in writing of spotted fever, which they

suspected as being a tick-borne disease, state "Several physicians, however, recognize in addition a mild type in which there are no spots. There is much difficulty in the accurate diagnosis of the mild type, and though its existence must be recognized yet during the investigation herewith reported, all of the examinations except one were made on cases of severe type. In Montana cases of the mild type of the disease, which show no spots, are as yet too indefinitely differentiated to permit of their inclusion with those of the severe type which invariably develop the eruption. That such cases exist there can be no doubt. They are never fatal."

It is to the careful studies of Major Charles F Kieffer at Fort D A Russell, Wyoming, in 1906, that we are indebted for the first exact knowledge of an intermittent, non-exanthematic tick-borne disease of short duration and no known mortality. Kieffer prefaced his paper with the recognition that "the older physicians in the Rocky Mountain regions have always insisted that there was a special type of fever indigenous to this section of the country. This fever or, as it appears to me, group of fevers has been given various names, but principally that of mountain fever. The group has simply been dismissed in recent years, although many good observers still hold that there is a type of fever which is neither malaria nor typhoid."²⁵

Kieffer recognized two types, one having three to seven recurrences of forty-eight hours duration marked by forty-eight hour intermissions and "another type, but not so common, in

which after the initial chill the temperature rises ladder-like for two or three days. These cases have more marked prodromes or more marked abdominal symptoms (abdominal tenderness and enlargement of the spleen) and present a clinical picture which is, at first, extremely suggestive of typhoid fever." Kieffer's paper should be read in the original.

After Kieffer's contribution, mountain fever attracted only local interest in Colorado and the adjacent parts of Wyoming and Utah. No notice was taken of it in medical literature until 1926 when F. E. Becker said that "certain symptoms of malaise, not typical of Rocky Mountain spotted fever, frequently follow tick bites in Colorado. Evidence supports the view that they are due to the tick bite, and are not part of the clinical picture of Rocky Mountain spotted fever. Many micro-organisms other than *D. tickettsi* are found in the ticks of Colorado."¹⁰⁴ In a later paper Becker says "An atypical infection following tick bite with characteristic constitutional symptoms, but without a skin eruption, is common in Colorado and is locally known as 'Colorado Tick Fever'. If this is an attenuated spotted fever, the definition of this disease must be modified to include cases without skin rash. Indolent ulcers frequently occur at the site of the tick bite."²⁰³

In 1929, R. R. Parker wrote "Public Health Service investigators have for several years been interested in a wood-tick-caused condition which occurs quite extensively in portions of Colorado and is far from uncommon in Wyoming. In sections of Colorado this

condition has been commonly known as 'mountain fever'. Compared to the usual typical cases of spotted fever it is relatively quite mild and at the present time it is uncertain whether it is a mild type of spotted fever or a distinct disease entity."¹⁹²

With respect to a Rocky Mountain spotted fever without an eruption, Dr. R. R. Parker in 1930 said " 'spotted fever without eruption', a diagnosis which we feel is purely presumptive and rarely justified " (Page 95-¹⁹¹).

From the title of a paper by Dr. F. E. Becker before the Boulder County (Colorado) Medical Society on May 8, 1930, on "Rocky Mountain Spotted Fever with Special Reference to Cases Without Rash," we gain the impression that Becker considers mountain fever and spotted fever to be the same disease but on what evidence we have been unable to learn.

SPIROCHETOSIS FROM ARCADIAN

In 1930 Burford Weller and G. M. Graham of Austin, Texas, described a group of three cases of a relapsing fever following infestation with the tick *Ornithodoros tunicata* acquired by some youths when they explored a cave in the Colorado River Valley, Texas. An unidentified spirochete was found in the blood in all cases, and a similar organism was recovered from a rabbit inoculated through the abraded skin with a crushed tick and thereafter violently ill. Graham, who later visited the cave, was bitten and was ill with a relapsing type of fever; a spirochete being recovered from his blood.

Serious constitutional reactions following bites of *Ornithodoros tunicata*

(A Duges) 1876 and *O talaja* (Guérin-Meneville) 1849, and *O coriaceus*, (C L Koch) 1844, have been known in Mexico for many decades⁸² For the present at least it is not thought proper to consider this argasid spirochetosis as identical with the non-exanthematic, intermittent tick-borne (mountain) fever of the northern Rockies, due to well marked differences in the vectors and the clinical courses of the diseases

DIFFERENTIATION OF THE TWO WOOD-TICK TRANSMITTED FEVERS OF THE ROCKY MOUNTAINS

Spotted fever is now recognized to follow more different clinical courses than the two classical types described prior to 1908^{4,31,41} However, this fact is not accorded sufficient notice in textbook and clinical literature Up to 1908 the two recognized types were *the benign (very slightly remitting) type in Idaho*, and *the short but malignant form in the Bitter Root Valley*, the latter (usually without remissions) running a constantly rising febrile course to hyperpyrexia and ending almost invariably in circulatory collapse between the fifth to eleventh day

A *very mild, ambulant type* with exanthem scanty or evanescent is now not infrequently recognized in Idaho and eastern Oregon It is said to run a prolonged course (between three and a half to four weeks)

A *moderately severe, protracted, severely emaciating type* of the disease, in which the daily remissions are better marked than in other forms, occurs where the disease is of intermediate violence as in Nevada Utah, and

Colorado This type may last four to five weeks and is sometimes called the chronic type.

Inasmuch as there are four readily recognizable clinical types of spotted fever, the different strains of the virus will excite symptoms in somewhat differing intensity and combination Thus onset may be abrupt or more gradual (but is always reasonably clear cut and never very gradual) The fever may terminate with abrupt or gradual lysis but never by crisis The fever has a tendency to produce hyperhidrosis early but a dry skin later in the course, but the degree of hyperhidrosis is, as with certain other symptoms and signs, somewhat conditioned by the patient's habitus During onset, vomiting occurs commonly in the types of moderate and severe intensity, but like some other symptoms is partly conditioned by the patient's habitus, thus occurring in some of the mildest cases and not occurring in some of the most severe Universal chilliness, without rigor, varying in intensity from distinctly noticeable to marked, almost invariably occurs Usually the chill (chilliness) is not a shaking, chattering rigor but is more persistent than in other fevers, often lasting three to four hours, and is devoid of 'creepy feelings'.

Stupor is an early and rather constant characteristic of the disease, even in its mildest forms, and a low (only very exceptionally violent) delirium occurs commonly The tone of the muscles increases rather than lessens (a feature not sufficiently noticed in the literature). This may account for the spastic inability to void Constipation is usual during the first two or

three days. It seldom gives way to diarrhea. Inability to protrude the tongue and to speak are, in the severer forms, curiously frequent signs after the first few days. Insomnia is always a troublesome feature.

The pulse is characteristically quite rapid (110 to 140) becoming easily compressible in the virulent form. Respirations are normal or slightly more rapid, the respiratory excursion not being reversed. Very pronounced congestion of the conjunctivae without lachrymation is an almost constant symptom in all types of the disease. Muscle aches and pains, especially of the extremities, and chiefly of the flexor groups, occur early, practically at the onset, and may be one of the first symptoms.

The rash, occurring from the end of the second day to the fourth day, may be described briefly as consisting of erythematous (usually somewhat cyanotic) ovoid to pseudomorbiliiform, lenticular macules, at first slightly raised above the surface of the skin. The rash first appears on the ankles and wrist and spreads up the limbs to appear on the back and then the abdomen and chest, usually sparing the neck and face, which however commonly takes on a puffed appearance. The rash persists well into convalescence, usually becomes more or less purpuric, and stains from it may last for months. Confluence occurs in severe cases but is not common.

The fever of spotted fever is continued, slightly remitting in the milder cases, or constant to slightly rising in the malignant cases. At onset it usually rises abruptly or sub-abruptly with one

or two slight remissions during the first twenty-four hours. The fever may become distinctly remitting after the first few days, and especially quite so in the latter course of the moderately severe, protracted cases but never does it completely abate until the terminal lysis. However, without a distinct undulant type or definite intermissions there are occasional fluctuations in the daily maxima and minima. *Distinct intermittency does not occur in spotted fever* although after the abrupt lysis there may be, following a subnormal temperature for a day, an after-fever of very slight degree and of one or two days duration.

A severe secondary anemia develops after the first week of the disease, and persists well through convalescence, and small gangrenous areas on external genitals, ears, pharynx and sometimes on digits occur as not uncommon terminal complications in the protracted, severe forms.

As for *mountain fever*, with its equally abrupt onset. Besides the well marked intermittent character of the fever, and its brief total duration (eight to sixteen days), and the absence of an exanthem, *mountain fever* differs from *spotted fever* in its lack of local symptoms such as conjunctivitis, pharyngeal engorgement and terminal gangrenous areas. The site of the tick-bite is commonly the site of an indolent ulcer which is not the case in *spotted fever*. We note in both a stuporous state and pronounced aches and pains in the muscles but in *mountain fever* the latter are referred mostly to the back and lower limbs, in *spotted fever* they are referred to

extremities. Insomnia is a troublesome feature in spotted fever but occurs only transitorily or not at all in mountain fever. Constipation and urinary retention due to vesical spasm occur in both diseases, but bronchial irritation is not noted in connection with mountain fever. The pulse, quite rapid in both at the onset, has a very decidedly greater tendency to slowness, even to a distinct bradycardia, in mountain fever than in spotted fever, in which it has a tendency to become very rapid and thready, especially in the severe forms. Convalescence is much quicker and more rapidly completed, often being dramatic, after mountain fever than after spotted fever, which is usually quite protracted. Nothing like so great a secondary anemia is produced by mountain fever compared to the fifty per cent erythrocyte and hemoglobin reduction of spotted fever. The tongue is dry, furrowed and thickly coated from the onset of mountain fever whereas during the first week or ten days of spotted fever it is swollen, somewhat moist and only slightly coated. Drenching sweats seem to be a little more common during the remissions of mountain fever than during the abrupt lysis of spotted fever.

Although the clinical differences between mountain fever and spotted fever could be caused by a difference in the strain of the virus it is our opinion that unless the two diseases are proven to be due to the same virus we have to recognize such a decided dissimilarity in their symptomatology and clinical course as to justify us in regarding them as separate disease entities.

THE RELATIONSHIP OF SPOTTED FEVER AND MOUNTAIN FEVER

Not until the immunologic relations of one disease to the other have been established will we have a secure basis for uniting these diseases or recognizing them as etiologically separate entities. Clinical study has gone about as far as it can. From the present observational aspect, the intermittent, non-exanthematic tick-borne disease has only one thing in common with spotted fever and that is the fact that it can be transmitted by the same species of tick. So also can tick paralysis and tularemia be transmitted by *Dermacentor andersoni*, and yet it is patent that they are different diseases from spotted fever, etiologically as well as clinically. Thus the fact of a vector common to spotted fever and mountain fever should not compel us to group them together, except perhaps as an epidemiologic expedient. For statistical purposes it would be eminently unwise to consider them the same disease, and this after all is one of the most practical tests.

By what means mountain fever will be more intimately compared to spotted fever we can not now predict, as it is not a serious disease and is not attracting scientific study. What we should learn is whether or not those who have had the intermittent, non-exanthematic tick-borne disease are immune to spotted fever. Obviously it would not be prudent to use a strain of spotted fever more virulent than the Snake River strain for a tick feeding experiment on one who had mountain fever but was known not to have had spotted fever. There are other

methods for testing the relationship. Blood drawn during the height of the intermittent, non-exanthematic disease can be injected into guinea-pigs immune to spotted fever and into those susceptible to spotted fever, and into men who have had and who have not had spotted fever, provided the donor is known to be not syphilitic. To try to give the benign disease, mountain fever to one immune to spotted fever by means of a tick attachment (feeding) experiment would be inconclusive if only negative data were acquired, as it would be extremely difficult to prove that the ticks used were virulent for mountain fever at the time of the attachment. The virus does not occur in all wood-ticks and its successful transmission is influenced, perhaps by phases of latency or other conditions. If the non-exanthematic, intermittent tick-borne disease can be established in a laboratory animal it is important that it be done so that the virus can then be transported more readily and maintained for study with greater certainty and convenience.

SUMMARY

For seventy-five years many physicians practicing in certain parts of the mountainous West have recognized a brief, seasonal, non-exanthematic, remittent fever with certain characteristic symptoms and no known mortality, which they have considered indigenous to the locality and different from typhoid fever, malaria or other known diseases, although confused with malaria or typhoid fever by some.

The early published reports are not

absolutely conclusive but a review of them leaves the impression that there were early observed cases of a fever, called mountain fever, that conformed to our present knowledge of the disease, and remain inexplicable on the basis of a plasmodial, enteroidal or undulant infection.

A seasonal, non-exanthematic remittent (occasionally continued) and intermittent fever of short duration and no known mortality, and conforming to the conception of mountain fever as understood in certain parts of the Rocky Mountain region was associated by Kieffer with a transmission by means of the bites of wood-ticks.

The virus of mountain fever has not been studied and the immunology of the disease with respect to spotted fever is not known.

The tick-borne non-exanthematic mountain fever has a clinical course characteristic and peculiar to itself and one not difficult to distinguish in the aggregate.

For clinical or statistical purposes it would be exceedingly unwise to identify mountain fever with spotted fever or undulant fever.

Until its course is identified or the immunological relationships of the disease are clearly established mountain fever should be considered to be a distinct disease entity.

Nosologically the tick-borne mountain fever resembles the dengue group of fevers somewhat more closely than the relapsing (spirochetal) fevers. The name American Mountain Tick-fever is proposed for it.

American Mountain Tick-Fever and Spotted Fever of the Rocky Mountains—Comparative Epidemiography*

By NOXON TOOMEY, M D , F A C P , *Palmyna, Mo*

PARALLEL study of mountain fever and spotted fever affords a most useful method for ascertaining their characteristics, for establishing comparisons and differentials between them, and for determining their respective positions in the social, economic and medical life of our times. Indeed, one might be led to take for granted that inasmuch as both diseases have the same arthropod vector, epidemiology, parasitology and prophylaxis would be identical for the two. Such is true to a large extent but as the diseases do not absolutely conform in the mechanics of their pathogenesis, it is important to compare them in a way that will visualize the differences in their pathodynamics. A common factor or foundation for the two diseases is found, but for each there is a separate superstructure indicating individuality. These differences reinforce our clinical observations concerning the dissimilar nature of spotted fever and American mountain tick-fever.

As very much more is known of spotted fever than of mountain fever it is not possible in the present state of our knowledge to compare the two

diseases in all respects. As it is important, however, to give the most complete picture possible of the epidemiology of spotted fever, important features of the latter will be discussed even when the comparable features of mountain fever are not known. Thus not only will spotted fever be made known more comprehensively but for the further study of mountain fever various suggestive viewpoints will be presented for elucidation.

EPIDEMIOLOGY

Spotted fever is not contagious nor inoculable from man to man by means of customary contacts. The virus can, however, penetrate the unbroken skin and has been known to do so under exceptional circumstances, such as in the handling of ticks in experimental work.^{1,2} Several laboratory workers have contracted the disease from handling infected material such as tick viscera, tick eggs and tick feces.³

Concerning the artificial inoculability of *mountain fever* no data is available. From the fact, however, that the virus does not have as great a latent or virulent immunity-producing phase as the spotted fever virus, and as *mountain fever* has been known to occur in larger outbreaks than spotted fever,⁴

*Submitted for publication, July 31, 1931.

seems that the virus of mountain fever has a greater certainty of transmissibility through the skin than that of spotted fever

For neither disease do fomites need be taken into practical consideration although it is not impossible that active virus persists for some days in dead tick material, and that the latter can be spread by fomites under extremely exceptional circumstances

Distribution *Mountain fever* is limited to an area within that of the spotted fever tick-area. According to present knowledge the inference is justified that the distribution of mountain fever is conditioned by most factors influencing the distribution of spotted fever and also by a factor peculiar to itself

Spotted fever is known to occur in the mountain fever area but in that area it is not quite as prevalent as in other portions of the *D. andersoni* distribution area. Thus, along the axis extending diagonally from the center of the State of Washington southeastward to the southeast corner of Colorado, and for a hundred miles on either side, the spotted fever occurs far more preponderatingly over the northwest two-thirds of this area, whereas mountain fever is limited (approximately) to the southeastern one-third. That the difference is not due to a change in the type of one and the same disease is evident from the fact that spotted fever when it does occur in the southeastern portion is clinically quite distinguishable from mountain fever and is substantially true to its type as existing in the north-west part of its area although causing somewhat more violent febrile symptoms when occur-

ring in the southeastern portion of its area^{26,178}

Spotted fever occurs in a western, Rocky Mountain or major endemic area, a minor or eastern-southeastern states endemic area, and sporadically elsewhere

The eastern area is from the southern border of New York to the northern border of Florida and from the Atlantic coast line westward to the Appalachian mountains

The western endemic area includes the southeastern quarter of Washington¹⁸⁰, the eastern half of Oregon¹⁹¹, several counties on the northern and (north) eastern border of California¹⁸⁰, all of Idaho except the extreme northern tip, all of Montana^{13,195}, all of Wyoming¹³⁵, the northern half of Nevada²⁸, the northern four-fifths of Utah⁵⁹, and the western three-fifths of Colorado. A characteristic is the especial prevalence of the disease in certain localities (valleys) of the area

In the above described area mountain fever is definitely known to occur only in approximately the lower and somewhat eastern half, namely in Colorado, Utah, Nevada and Wyoming, although it seems to occur to a limited extent somewhat northwestward of the main endemic area, namely in the southern portion of Idaho and Oregon. However, the northern portion of the *D. andersoni* distribution area, namely Montana and the adjacent parts of Idaho and Washington have not been sufficiently investigated for mountain fever. Mountain fever has not been reported from the eastern-southeastern states endemic area of spotted fever

Recent Spread For *spotted fever* the area of known distribution has increased greatly since 1904, and particularly since 1914. It is indubitable that spotted fever has lately occurred for the first time in areas where medical men were sufficiently skilled to have recognized it had it occurred at an earlier date. For instance in

Montana, until 1914, infection was definitely known in but four counties, Missoula, Ravalli, and Granite, west of the continental divide, and in Carbon county, bordering Wyoming in the south portion of the eastern part of the state. It has now been reported from thirty-one counties in the eastern portion of Montana. It has spread to South Dakota (first reported case in 1915), to North Dakota (first reported case in 1919) and Nebraska (first reported case in 1931)²¹⁵

Maver and others have shown that spotted fever can be transmitted by ticks other than *D. andersoni*, and as ticks that bite man are widely distributed over the United States, Canada and Mexico it is not improbable that spotted fever will eventually have a wider area of distribution.

As ticks do not migrate for any appreciable distance the recent sudden spread of ticks containing virus is probably to be partly accounted for by interstate commerce in live-stock, particularly in sheep, to the wool of which ticks cling for several days before being killed by the sheep's grease. However it would not be correct to suppose that the spotted fever area has been widened solely through the agency of man (commerce, etc.) as the area has undoubtedly been widening slowly through the migration of infected rodents, by means of the rabbit-tick and the widening dissemination of infected tick eggs by natural means.

It is interesting that the spread of spotted fever to the plains areas of Montana and Wyoming has not (according to available reports) carried mountain fever with it, notwithstanding that the western half (particularly

the southwestern quarter) of Wyoming has for years been heavily infested with mountain fever. In fact, by comparing early reports with the present known distribution of mountain fever, *the area of mountain fever appears to have diminished in extent*. This has occurred in the more densely inhabited (cultivated) portions of Colorado and Wyoming, and partly in the Black Hills, and is undoubtedly to be accounted for by the clearing of underbrush and the other tick-eradictory measures incidental to intensive farming, whereas the virus does not seem to be spread among rodents by the rabbit-tick.

Seasonal Characteristics. Both spotted fever and mountain fever are seasonal diseases being limited by the occurrence of predatory wood-ticks and dog-ticks in nature. The tick season is from the first warm days of spring (March) to somewhat after the maximum heat of summer (about the middle or end of July) although cases have been known to occur not uncommonly as late as September, and rarely at other times of the year. The majority of cases occur in April, May and June, especially in May. Obviously there is some variation from year to year according to climatic conditions and also the seasonal range varies for different localities according to their latitude, altitude and exposure to sun, wind and rain-fall.²¹⁶

Both spotted fever and mountain fever have been observed in rare instances during the cold weather of late winter (middle of December to end of February). This exceptional seasonal incidence can be accounted for by dwellings having become infested

with virulent ticks during the preceding summer or autumn. Hibernating through the winter, these ticks in the dwellings become stimulated to activity at a date earlier than usual by the dwellings becoming over-heated.

Climatic conditions as factors in tick prevalence are important as they operate directly on the life-cycle of the tick and on the pabulum that supports the tick⁸⁷. Thus moderate warmth with moderate moisture and protection from abundant sun glare are the optimum conditions for the wood-tick, any departure in either direction diminishing their prevalence.

Whether there is a distinct difference between the climatic requirements of mountain fever and spotted fever cannot be asserted with full assurance as too little is known of mountain fever, but such data as are at hand seem to indicate that mountain fever is found in a higher and drier climate than is spotted fever, and that it has a longer seasonal incidence (cases being observed not uncommonly in August and early September) which may mean that the virus of mountain fever is more resistant to heat or sunlight, or both, than that of spotted fever.

Geophysical Characteristics Formerly much significance was attached to spotted fever being particularly prevalent in certain deep, isolated mountain valleys characterized by a spring freshet or water-shed from the melting snows on the upper mountain reaches¹⁰. These spring freshets serve to increase the prevalence of the disease by irrigating the underbrush in which the ticks hibernate and by washing the ticks down to the foot-hills. Sage-brush

of woods with underbrush that is fairly dry the greater part of the time, and shaded from constant direct sun glare can become heavily infested. Areas subjected to constant or periodically recurring strong wind currents are not so favorably situated for harboring heavy tick infestation as are the protected sides of the valleys, and this is why the protected sides of valleys are more morbidic than the exposed sides.

Relation to Flora For *spotted fever* the endemic area is not conditioned by the topographical distribution of a special plant or plant relationship, although underbrush, particularly sage-brush, seems especially agreeable to the wood-tick⁷⁴.

Mountain fever is much more prevalent in wooded areas than in sage-brush plains and may tentatively be said to be confined to the upper timber regions of mountain passes and canyons.

Relation to Fauna That *spotted fever* is indigenous to small rodents, particularly chipmunks, was confidently anticipated early in the study of the disease⁷², but the latest serologic work has shown that while it does occur naturally among wild rabbits, ground squirrels, woodchucks and probably other small rodents (which act as the natural reservoir), it is actually a rare disease among them, and usually benign. These animals become more or less healthy carriers and are largely responsible for maintaining the disease in nature. Hence rodent extermination is a necessary part of any plan for exterminating the disease. The large wild animals, elk, deer, and mountain goat, and the large domestic animals

horse, cow, sheep and dog are immune¹¹²

That *mountain fever* is more especially related to the mountain goat and mountain rat than the gopher and wild rabbit populations has not been proven but seems likely from the character of the localities where it is most endemic

For both diseases, infection of man may occur at any time of the day or night, and is not especially favored by any part of the diurnal cycle

Age Incidence In sections where families live in infected districts there is no characteristic age incidence for either mountain fever or spotted fever. Actually, however, cases are far more common among adults than among children, and this is especially true for mountain fever. This difference in age incidence is largely due to increased exposure to wood-ticks by reason of the occupations of the adults which occasion them to enter the wooded mountain sides as trappers, rangers, surveyors, miners, lumbermen, etc.¹²¹

Sex Incidence Differences in exposure to ticks by reason of occupation result in many more cases occurring in men than in women. Cases in women are often caused by ticks brought home by the men and boys of the household.

Occupational Incidence *Spotted fever* occurs mostly among persons engaged in agricultural pursuits, and except under special conditions is most common in persons associated with the various phases of the live-stock industry, especially the handling of sheep. Cases also occur, however, among forest service employees, prospectors, hunters, and others whose occupation or the pursuit of pleasure or profit

takes them into tick-infested sections¹⁰⁵

Mountain fever is associated more decidedly with the timber industry, hunting and trapping in the mountains, and other mountain pursuits, and in this respect it differs distinctly from spotted fever. Among the early reports of army surgeons in the mountainous West, mountain fever was commonly referred to, whereas spotted fever was observed only rarely, and in certain circumscribed localities (Wind River Valley, Bitter Root Valley, etc.)

Economic Importance *Mountain fever* has no economic importance other than that which attaches to any benign fever of short duration. With *spotted fever*, however, it is vastly different. No one who is not in close contact with the spotted fever situation can appreciate the degree to which spotted fever is dreaded in the sections in which it is endemic. Before the commencement of the tick season many fertile mountain valleys become temporarily depopulated, most families moving out until after the middle of July. Naturally such hazards and necessity for inconvenience depress property values and hamper development. The mental worry to which tens of thousands of families are subjected each year during the tick season restricts the enjoyment of the opportunity for out-door life which constitutes one of the greatest natural assets of the Rocky Mountain region. Because of the far greater number of persons involved these considerations far outweigh the economic loss due to the actual occurrence of human cases. The latter is a serious concern, since, though recovery occurs there is, there

or less protracted period of convalescence, often of several months, during which it is often impossible for the patient to resume his usual occupation¹⁸⁷

The marked prevalence of spotted fever among sheep herders and others concerned with range management of sheep is frequently a real problem for wool growers, and in some sections is a factor which merits and receives serious consideration^{91,104}

THE VIRUS IN NATURE

Reservoirs. Investigations in Montana have shown the following rodents to be susceptible to spotted fever: the Columbian ground squirrel, *Citellus columbianus*, the side striped squirrel, *Callospermophilus leucurus cinereascens*, the woodchuck, *Marmota flaviventris*, the pine squirrel, *Sciurus richardsoni*; the white bellied chipmunk, *Eutamias g. umbrinus*, the yellow bellied chipmunk, *Eutamias b. luteiventris*, the wood rat, *Neotoma cinerea*, the snowshoe rabbit, *Lepus harrisi*, the cottontail rabbit, *Sylvilagus nuttali*, the white tailed jack rabbit, *Lepus t. campestris*, the prairie dog, *Cynomys l. ludovicianus* (Ord), the badger *Taxidea taxus* (Schreber); and the weasel, *Putorius arizonensis*

Character of the Virus The virus of spotted fever has been described as having two phases, a non-virulent phase capable of producing immunity but incapable of producing clinical manifestations of infection, and a virulent phase that causes the clinical manifestations of spotted fever and also permanent (or a long lasting) immunity. This bi-phasic character of the virus is the probable explanation of

certain features of the disease that were for long inexplicable. However, the biodynamics of this character of the virus have not yet been elucidated. The virus of spotted fever does not pass through a Berkefeld filter.

The virus of *mountain fever* seems not to have any biphasic character. It possibly can be identified with the filter passing virus recovered from the wood-tick (*D. andersoni*) by Noguchi.

Virulence *Mountain fever* does not differ greatly in virulence from year to year or with respect to the locality where acquired. There are minor variations in the clinical course of the disease in different outbreaks and there are two main varieties of clinical type, the relapsing type and the typhoidal type. Several clinicians have, however, remarked upon the great similarity of all cases of American mountain tick-fever as observed in a given epidemic.

Spotted fever is unique in the fact that the virulence varies greatly in different localities but that the virulence of the infection in any locality is reasonably constant. The areas of greatest known virulence are the west side of the Bitter Root Valley in western Montana, a small section on Kirby Creek near Thermopolis, in Hot Springs County, Wyoming, and an area in the Wind River mountains in Fremont County, Wyoming. In these sections the mortality is high, not infrequently reaching 80 to 100 per cent. The area of mildest infection is in the Snake River Valley in southern Idaho where the mortality seldom exceeds five per cent. Areas of intermediate severity occur in other sections of the Rocky Mountain region. Ambulatory cases

are not uncommon in southern Idaho and eastern Oregon¹⁸⁷

Mechanics of Transmission For both mountain fever and spotted fever the method of transmission is grossly the same, namely a fixation (bite) of a virulent tick in the human skin for the purpose of engorgement. In the instance of both diseases the virus is transmitted not mechanically, or by the feces, but in the suctorial juices inoculated by the tick during the process of engorgement. There are, however, slight time differences between spotted fever and mountain fever. In spotted fever the tick, even though potent with a highly virulent strain of spotted fever, does not become infective under one and three-quarter hours of fixation. The high proportion of non-immunes infected during certain epidemics (from one-fourth to one-half) leads to the inference that so long a time for infectivity to develop is not present in mountain fever.

ACTUAL AND POSSIBLE VECTORS

Spotted fever is known to be transmissible to man by means of the following species of ticks: the western wood tick *Dermacentor andersoni*, Stiles, 1908¹⁵², the California tick, *Dermacentor occidentalis*, Marx, in Utah by *Parumapertus marginatus*, by *Dermacentor albipictus*, Packard, in the northern plains by *Amblyomma americanum* (Linnaeus), and in the eastern-southeastern states by the dog-tick, *Dermacentor variabilis* (Say). Banks, 1908. These ticks also feed on small rodents. No infected *D. albipictus* have been recovered from nature in spite of repeated tests.

Haemaphysalis leporis - palustris Packard, a rabbit-tick, feeds on all species of rabbits and on game birds but is known not to feed on man. It is, however, a potent and very serious factor in spreading spotted fever in nature, and indirectly in spreading the disease to man.

It is not impossible that ticks unstudied from this aspect, such as the animal (and human) ear tick, *Otiobius megnum*, Duges, 1883, and other species of the Argasidae may some day be found to transmit spotted fever to man.

Whether spotted fever can be transmitted by species of the Clinocoridae (bed bugs) or the Siphonaptera (lice) has never been proven or disproven.

Nymphs of *D. andersoni* have twice been known to infect infants, but usually only adult ticks are known to feed on man. The disease has been transmitted to small rodents by means of larval and nymphal ticks, and these are not uncommon vectors under natural conditions.

American mountain tick-fever is not known to occur outside of the distribution area of *D. andersoni*. In fact it does not occur over the whole of the *D. andersoni* distribution area; the northwestern half of the latter apparently not being concerned with mountain fever. In this connection it is well to note that the common wood-tick of Idaho and Nevada had early in uncertain taxonomic place at one time being confounded with *D. occidentalis* and at another time being set up as a separate species *D. medialis*. These varietal differences within *D. andersoni* apparently occur but whether the western variety *D. andersoni* or *D. medialis* is incapable of transmitting

or less protracted period of convalescence, often of several months, during which it is often impossible for the patient to resume his usual occupation¹⁸⁷

The marked prevalence of spotted fever among sheep herders and others concerned with range management of sheep is frequently a real problem for wool growers, and in some sections is a factor which merits and receives serious consideration^{91,104}

THE VIRUS IN NATURE

Reservoirs Investigations in Montana have shown the following rodents to be susceptible to spotted fever: the Columbian ground squirrel, *Citellus columbianus*, the side striped squirrel, *Callospermophilus leucurus cinerascens*, the woodchuck, *Marmota flaviventris*, the pine squirrel, *Sciurus richardsoni*; the white bellied chipmunk *Eutamias q umbrinus*, the yellow bellied chipmunk, *Eutamias b luteiventris*, the wood rat, *Neotoma cinerea*, the snowshoe rabbit, *Lepus harrisi*, the cottontail rabbit, *Sylvilagus nuttali*, the white tailed jack rabbit, *Lepus t campestris*, the prairie dog, *Cynomys l ludovicianus* (Ord), the badger, *Taxidea taxus* (Schreber); and the weasel, *Putorius arizonensis*

Character of the Virus The virus of spotted fever has been described as having two phases, a non-virulent phase capable of producing immunity but incapable of producing clinical manifestations of infection, and a virulent phase that causes the clinical manifestations of spotted fever and also a permanent (or a long lasting) immunity. This bi-phasic character of the virus is the probable explanation of

American mountain tick-fever is not known to occur outside of the distribution area of *D. andersoni*. In fact it does not occur over the whole of the *D. andersoni* distribution area; the northwestern half of the latter apparently not being concerned with mountain fever. In this connection it is well to note that the common wood-tick of Idaho and Nevada had early an uncertain taxonomic place, at one time being confounded with *D. occidentalis* and at another time being set up as a separate species *D. modestus*. Thus, varietal differences within *D. andersoni* apparently occur but whether the western variety *D. andersoni sensu modestus* is incapable of transmitting

mountain fever remains to be proved

Whether under natural or laboratory conditions the virus of mountain fever can be transmitted to man by an arthropod other than *D andersoni*, remains to be ascertained.

Incidence of Tick Virus in Nature
In endemic areas of *spotted fever*, only about one out of every two hundred ticks caught at random are virulent for spotted fever

What proportion of the ticks in an endemic area of *mountain fever* are able to infect man is not known, but from the rapidity with which some epidemics of mountain fever develop, and the high percentage (twenty-five to fifty per cent) of cases among known non-immune groups, it would appear that most ticks in mountain fever endemic area are able to transmit mountain fever to man.

MORBIDITY STATISTICS

Spotted Fever. The morbidity rate varies for different localities, and in a given locality to some extent from year to year, although the virulency in any

given locality is reasonably constant
The following table gives the number of cases reported to the Boards of Health in the States and years indicated

No statistics have been published as to what per cent of the population in an endemic area have an acquired immunity, but in the southern part of Idaho a very large per cent of the sheep herders are known to have recovered from the mild form of spotted fever.

As to *mountain fever* we have no abundance of satisfactory records concerning morbidity, but in certain portions of western Colorado, south-western Wyoming and north-eastern Utah, mountain fever undoubtedly has a very high morbidity rate Major Kieffer wrote of it as though it occurred commonly at Fort D S Russell (south of Cheyenne, Wyoming), but gave no statistics

At Fort Bridger, Wyoming, Capt Charles Smart, U. S A , found that over an eight year period of time a military command with a mean strength averaging 145 men for the six months (March to August), had cases per

Washington,	0 22 or for affected (Eastern) portion	0 50
States with approximately one-tenth state-wide distribution		
California,	0 30 or for affected (North-east) portion	3 00
South Dakota,	0 15 or for affected (Western) portion	1 50

thousand of mountain fever as follows in March, 1 49, in April, 1 62, in May, 5 60, in June, 13 89, in July, 9 47, and in August, 4 26, totaling 36 33 for the tick season, or an incidence of 5 2 cases a year for a command of 145 men. The rate of 3633 per hundred thousand is 85 times the Idaho, or maximum known morbidity rate for spotted fever. Fort Bridger was undoubtedly a heavily infested locality where the men were well exposed and where the varying composition of the command from year to year gave little opportunity for the population to become stable and immune. Errors in diagnosis may have increased the rate somewhat but not enough to raise it 85 times above the state-wide Idaho rate. Indeed,

that only five cases a year were diagnosed as mountain fever is excellent evidence that rheumatism, bronchitis and other common ailments were not called mountain fever just because observed at high altitudes, as has been alleged by some.

In Colorado the reported cases of mountain fever slightly exceed those of spotted fever but the comparison is very misleading as most cases of spotted fever are reported, but undoubtedly a small part only of the cases of mountain fever owing to their being benign and frequently overlooked or incorrectly diagnosed.

MORTALITY STATISTICS

Mountain fever has no known mortality.

TABLE 3
Recent Montana Statistics

Year	No. of Cases	Deaths	Mortality Rate
1922	58		
1923	48		
1924	44		
1925	31	10	33%
1926	32		
1927	35	5	14%
1928	29		
1929	20	7	35%

Annual average (whole state) 1914 to 1928 31 cases per year, average of 9 deaths per year. From 1917 to 1926 there were 369 cases with 89 deaths, or a death rate of 40 34 per cent. Mortality rate for Bitter Root Valley, 1916-1918, children, 50 per cent, adults 84 91 per cent, all cases, 76 81 per cent.

mountain fever remains to be proved. Whether under natural or laboratory conditions the virus of mountain fever can be transmitted to man by an arthropod other than *D andersoni*, remains to be ascertained

Fort Bridger was undoubtedly a heavily infested locality where the men were well exposed and where the varying composition of the command from year to year gave little opportunity for the population to become stable and immune. Errors in diagnosis may have increased the rate somewhat but not enough to raise it 85 times above the state-wide Idaho rate. Indeed,

that only five cases a year were diagnosed as mountain fever is excellent evidence that rheumatism, bronchitis and other common ailments were not called mountain fever just because observed at high altitudes, as has been alleged by some.

In Colorado the reported cases of mountain fever slightly exceed those of spotted fever but the comparison is very misleading as most cases of spotted fever are reported, but undoubtedly a small part only of the cases of mountain fever owing to their being benign and frequently overlooked or incorrectly diagnosed.

MORTALITY STATISTICS

Mountain fever has no known mortality

TABLE 3
Recent Montana Statistics

Year	No of Cases	Deaths	Mortality Rate
1922	58		
1923	48		
1924	44		
1925	31	10	33%
1926	32		
1927	35	5	14%
1928	29		
1929	20	7	35%

Annual average (whole state) 1914 to 1928 31 cases per year, average of 9 deaths per year. From 1917 to 1926 there were 369 cases with 89 deaths, or a death rate of 24 34 per cent. Mortality rate for Bitter Root Valley, 1916-1918, children, 50 per cent; adults 84 91 per cent, all cases, 76 81 per cent.

Spotted fever prior to 1910, statistics were available only for Idaho and Montana. The best available statistics gave for Idaho a rate fluctuating from year to year between 4 per cent and 7 per cent (Maxey's average, 4.86 per cent) and for Montana (Bitter Root Valley) from 40 per cent to 70 per cent with occasional annual extremes of 35 per cent to 100 per cent.

Next to Montana in order of mortality Wyoming (1922-1926) 22.80 per cent, Colorado (1913-1926) 18.18 per cent, Oregon (1913-1926) 17.28 per cent, Nevada (1911-1926) 11.81 per cent, Washington (1912-1926) 11.11 per cent, California (1903-1926) 10.53 per cent, Idaho 4.86 per cent. Average (uncorrected) 19 per cent, corrected by weighting, 12.4 per cent. Mortality rate among American Indians (as reported by Dr. Welty) Arapahoes, 20 per cent, Shoshones, 16.6 per cent.

The annual loss of life from spotted fever in the western endemic area now closely approximates one-eighth (12.5 per cent) of 600 cases a year, or between 70 and 80 deaths annually. With the addition of the deaths from spotted fever in the eastern-southeastern states endemic area the total for the whole country is about 100 to 110 deaths annually.

The mildest infection is in the Snake River Valley in Idaho where the mortality seldom exceeds 5 per cent.

Within the eastern-southeastern states endemic area at least 93 cases were known to occur in five states and the District of Columbia in the Spring and Summer of 1930 with 21 deaths—a case fatality rate of 22.6 per cent. In the Rumranch-Dyer-Badger selected

series of 50 cases, there was death of seven patients or 14 per cent.

The areas of greatest virulence are on the west side of the Bitter Root Valley in western Montana, a small section of Kirby Creek near Thermopolis in Hot Springs County, Wyoming, and an area in the Wind River mountains in Fremont County, Wyoming. The mortality in these sections not infrequently reaches from 80 per cent to 100 per cent. In southern Idaho near Soda Springs, an area of 100 per cent mortality was formerly known, but no cases have been reported since 1903. A group of very virulent cases was reported from Boise, Idaho, in 1929.

Of five consecutive cases occurring as laboratory infections among unvaccinated laboratory workers, all died.

SUMMARY

The epidemiography of two tick-borne diseases, each clinically distinguishable from the other, is found not to be conformable in all respects.

The mountain or more benign fever has been reported only from an area within the range of distribution of spotted fever, but it has not been observed over the whole of the spotted fever area of the Rocky Mountain region, nor is it known to occur in the eastern-southeastern states area of spotted fever.

Mountain fever is apparently limited by barriers peculiar to itself as it has not recently spread, or been carried, into new localities as has spotted fever. In fact, while the distribution area of spotted fever is slowly spreading, that of mountain fever is apparently less than it was formerly.

American mountain tick-fever is predominantly acquired within the upper timber reaches of the mountain valleys, and for the most part at a distinctly higher altitude than spotted fever, which is a disease of the valleys and inter-mountain plateaus whereas mountain fever is most prevalent in the timbered regions and high mountain passes

A longer seasonal incidence is observed for mountain fever than for spotted fever

Mountain fever has, in ratio to population, a very much greater prevalence than the largest morbidity rate known for spotted fever, which fact may indicate either a greater tick infestation ratio or that the virus of

mountain fever is not subject to a phase of latency as is that of spotted fever

Spotted fever is a seriously incapacitating disease with an average mortality of 12.4 per cent, and great economic importance, whereas mountain fever is a benign disease of no known mortality and trifling economic importance

Neither the virus nor the natural reservoirs of mountain fever are known but from data at hand it seems reasonable to suspect that rabbits, spermophiles, prairie dogs and chipmunks are immune to the disease, and that the reservoir should be looked for in mountain rats, badgers, and probably squirrels

Thrombo-Angiitis Obliterans Among Persons Past Middle Age*†

By BAYARD T. HORTON, M.D., F.A.C.P., and GEORGE E. BROWN, M.D.,
F.A.C.P., Rochester, Minn.

THROMBO-ANGIITIS obliterans usually occurs among men between the ages of twenty-five and fifty years. In a recent study of 150 proved cases by Brown and Allen the youngest patient was aged seventeen years and the oldest sixty-four, only two in the series were more than sixty years. Four other patients have since been observed at the clinic: a woman aged sixty years², a man aged sixty-three years with involvement of the left hand and both lower extremities, a man, aged sixty-five years, who gave a typical history of intermittent claudication in the arches and muscles of the calf for a period of thirty years, and a man, aged seventy-three years, the oldest patient with this disease observed at The Mayo Clinic, and, so far as we know, the oldest proved case on record.

With early diagnosis, improved methods of treatment, and the prophylactic measures which are being carried out in these cases, it is highly probable that a larger percentage of patients will reach the later decades of life without amputation. It is common to find arteriosclerosis of the extremities

of patients aged from fifty to sixty years, combined lesions of thrombo-angiitis obliterans and arteriosclerosis are also commonly found in this age group, and either lesion may predominate in a given case. Patients with thrombo-angiitis obliterans in the sixth and seventh decades of life represent a very small percentage of the total number with this disease, as is evidenced by the fact that only six patients aged more than sixty years were observed in a series of more than 500.

REPORT OF CASES

Case 1 A man, aged sixty-three years, registered at The Mayo Clinic June 4, 1926. His chief complaint was pain in the left foot. His health had always been good. He had been an excessive user of tobacco for many years. Five years prior to admission small painful, raised reddish and bluish lumps along both legs developed. With rest, the condition cleared in two or three months. Two years later pain, tenderness and swelling of both legs developed. This had disappeared, by rest and elevation of the extremities, at the end of two weeks. In September, 1923, an ulcer appeared on the fifth right toe. It failed to heal and caused excruciating pain. The toe was amputated in February, 1924. The wound healed promptly and the patient went back to work feeling perfectly well and remained well until May or June, 1925. At this time a sore spot appeared on the distal plantar surface of the left foot, associated with intermittent pain

*Submitted for publication April 3, 1931.

†From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

He continued to work most of the time until October 1, 1925, when a painful ulcer developed between the fourth and fifth toes, which did not heal. All of the toes on the left foot were amputated October 30. There was incomplete healing, and two discharging sinuses were still present at the time of admission to the clinic. Considerable pain was present. He had had intermittent claudication pain in the arch of the right foot for eight months. He had had weakness in the left hand for three months, when he attempted to work. Paresthesia was not observed.

The general examination was essentially negative, except for the condition of the extremities. The systolic blood pressure was 136 and the diastolic, 90, in millimeters of mercury. The right radial and ulnar arteries pulsated normally, but pulsations could not be felt in the left radial and ulnar arteries.

Definite postural color changes in the hands were not observed. Small pulsations could be felt in both femoral arteries, but pulsations were absent in both popliteal, both dorsalis pedis and both posterior tibial arteries. There were two small draining sinuses in the stump of the left foot. With the feet elevated, there was pallor, graded 1 to 2 of the right foot and graded 3 to 4 of the left foot. When the feet were lowered to the dependent position, there was rubor, graded 3, of the toes of the right foot in thirty seconds, and rubor, graded 4, of the left foot in three minutes. This indicated a slow return of blood to the left foot. Both feet felt cold. There was atrophy, graded 1, of the left thigh and leg. The neurologic examination showed a decrease in sensation of touch, pain and temperature, graded 2 to 3. The other neurologic data indicated arteriosclerosis of the central nervous system. Examination of the

FIG. 1. Cross section of the posterior tibial artery at the level of the ankle. The lumen is occluded by a recent partially organized cellular thrombus, in which lymphocytes and endothelial leukocytes are the predominating cells. A few polymorphonuclear leukocytes are present. Calcification of the wall of the vessel is not present (hematoxylin and eosin stain, $\times 35$).

urine and the Wassermann reaction of the blood were negative. The hemoglobin (Dare) was 70 per cent, erythrocytes numbered 4,310,000, and leukocytes 9,700 in each cubic millimeter of blood. The concentration of urea was 34 mg for each 100 cc of blood, and the creatinine 11 mg. The glucose tolerance test was negative. The return of phenolsulphonphthalein was 45 per cent in two hours. Roentgenograms of the legs were negative for calcified vessels.

One intravenous injection of triple typhoid vaccine was given, with a rise in systemic temperature of 3.6°F , but there was no rise in the surface temperature of the feet. Because of the patient's age, the severity of the pain, the prolonged healing with draining sinuses, and the absence of a rise in surface temperature in the left foot following the typhoid vaccine, amputation of the left leg was advised, but was refused. The patient went home eight days after admission.

Four months later the patient's home physician stated that the two sinuses had closed approximately half, he felt that amputation of the left leg was advisable. In July, 1927, the patient wrote that one sinus had entirely closed and that the other one had practically closed. He was free from pain and had gained 21.5 pounds in weight. He stated that a good pulse could be felt in front of the left ankle. In July, 1929, he again wrote that his general health was excellent and that the left foot had entirely healed. The foot still felt tender, but he was able to walk with the aid of a crutch.

A diagnosis of thrombo-angitis obliterans was made in this case because of the long history, the observations at general examination, especially the involvement of the left arm with occlusion of the left radial and ulnar

FIG 2 A higher power of figure 1 showing more cellular detail and representing the rectangular area in figure 1 (hematoxylin and eosin stain $\times 150$)

arteries, the history of chronic, relapsing superficial phlebitis, and the later course of the disease. Occlusion of vessels of the hand is common in cases of thrombo-angiitis obliterans but is extremely rare in arteriosclerosis. Many patients with thrombo-angiitis obliterans with ulcers and trophic lesions could probably avoid amputation of the involved extremity, if they were willing to endure pain as this patient did. In many of our cases amputation is done because of pain rather than because of the extent of the gangrene or of the trophic changes.

Case 2 A man, aged sixty-five years, registered at The Mayo Clinic October 23, 1929. He complained chiefly of intermittent pain in the legs, and hemoptysis. He had smoked an average of seven small cigars daily since the age of twenty. For the last thirty years he had had arch fatigue and pain of the intermittent claudication type, and had worn many arch supports without relief. For the last fifteen years he had had mild intermittent claudication in the calves. At the time of admission he could walk only two city blocks without this pain. Rest for a few minutes always gave prompt relief. During the last year he had complained of cold feet, and observed that they were blushed when in the dependent position. For the last four months he had intermittent rest pain in the first and second left toes. Seven

FIG. 3 Cross section of the posterior tibial artery from a subject with arteriosclerosis. Deposits of calcium salts (c) are present in the media (b). The intima (a) is thickened and is comparatively acellular (hematoxylin and eosin stain $\times 35$).

months prior to admission productive cough frequently with blood-tinged sputum developed following a "cold" On a few occasions he had coughed up 30 c.c. or more of bright red blood There was no definite history of superficial phlebitis

The patient appeared to be moderately well nourished, was approximately 5½ feet in height, and weighed 130 pounds The thorax was barrel-shaped, with definite limitation in expansion Râles were not present either before or after expiratory cough Roentgenograms of the thorax showed ancient healed tuberculosis at the right apex Examination of the sputum was negative for the bacillus of tuberculosis The possibility of hemoptysis from a small area of bronchiectasis was considered The heart showed compensatory cardiac hypertrophy, graded 1

The systolic blood pressure on admission was 175 and the diastolic 90, in millimeters of mercury While the patient was under observation in the hospital the systolic pressure was 130 and the diastolic 60 All of the palpable vessels in the upper extremities pulsated normally Both femoral arteries pulsated normally, and slight pulsation could be felt in the right popliteal artery, but pulsations could not be felt in the left popliteal artery or in the arteries of the feet The arches in both feet appeared normal With elevation of the feet, there was moderate blanching of the toes of the left foot With the feet in the dependent position there was rubor, graded 1, of the toes of the right foot, graded 2, of the left foot, and moderate cyanosis of the second left toe Examinations of the urine were negative The con-

FIG 4 Cross section of the dorsalis pedis artery The lumen is occluded by a partially organized thrombus which has been partially canalized There is absence of calcification in the wall of the vessel The internal elastic membrane (a) appears normal (hematoxylin and eosin stain x80)

centration of hemoglobin was 17.6 gm in 100 c.c., and the leukocytes numbered 9,100 per cubic millimeter. The concentration of blood urea was 34 mg in 100 c.c., and the blood sugar was 90 and 78 mg. The electrocardiogram was essentially negative. The return of phenolsulphonphthalein was 50 per cent in two hours. Roentgenograms of the feet and legs were negative for calcified vessels and for lesions of bone.

Radiant heat was applied to the legs for five to eight hours a day, and postural exercises were carried out three times daily. Intramuscular injections of typhoid vaccine were also given. The patient was instructed to restrict physical activity to the point of not producing pain in the lower extremities. Because of the thirty-year history of intermittent claudication (arterial closure), the slow onset of the disease, and the favorable

response to treatment, we believed that the prognosis was fairly good for preservation of the extremities. However, a letter from the patient dated March 24, 1931, stated that during the past six months the left leg had been amputated (apparently below the knee). The stump did not heal and a second amputation above the knee was necessary.

The long history of occlusive vascular disease beginning at the age of thirty-five years, and the absence in the roentgenogram of evidence of calcification of the vessels make the diagnosis of thrombo-angitis obliterans reasonably certain. The early use of arch supports is also suggestive. This history is the longest of this disease which is on record at The Mayo Clinic.

FIG. 5. Cross section of a deep vein of the left leg. The lumen is occluded by an ancient thrombus which has been canalized (Weigert's elastic tissue stain $\times 40$).

Case 3 A man, aged seventy-three years, was under observation at The Mayo Clinic in April, 1907, November, 1915, and March, 1929. Symptoms referable to the hands and feet were first observed in 1903. These consisted of the three-phase color reaction, white, red and blue, when the hands were exposed to cold. In 1906 the fifth right toe was amputated elsewhere for an unhealed ulcer. At the time of his first admission in 1907 he had an unhealed ulcer on the right great toe. The toe was amputated. During the next five or six years two or three similar ulcers developed which required from six to eight months to heal. At admission in 1915, there were ulcers on the second right and the first and fifth left toes, which had been present for approximately ten months.

Both feet appeared hyperemic in the dependent position. The general examination was otherwise essentially negative. The systolic blood pressure was 126 and the

diastolic 86. Examinations of the urine were entirely negative. The concentration of hemoglobin was 89 per cent and the leukocytes numbered 10,800. The Wassermann reaction of the blood was negative. A roentgenogram of the thorax was negative, except for slight enlargement of the heart, graded 1. Roentgenograms of the feet were negative. It was believed at this time that the ulcers were due to obliterative arterial disease, but record was not made regarding pulsations in the arteries of the feet. However, rest, with the feet in a horizontal position, was advised until adequate collateral circulation was established.

During 1918 and 1919 the second right and the third left toes were amputated elsewhere for unhealed ulcers. It required from two to twelve months for these amputation wounds to heal. During the course of the patient's illness, he had approximately twelve ulcers on the tips of the toes. Fourteen

FIG 6 Cross section of a small artery. Cellular thickening of the intima is shown (hematoxylin and eosin stain $\times 135$).

months prior to his third admission, March 6, 1929, an ulcer developed at the base of the left great toe, which gradually increased to about 2 cm in diameter. There was little pain associated with these ulcers. For a period of twenty years, he had noticed an occasional small nodule beneath the skin. Whether these represented areas of superficial phlebitis could not be determined from the history. There was no definite history of intermittent claudication, although for a period of more than twenty years he did very little walking, and always took the best of care of his feet and legs. He had smoked an average of three cigars daily for the last fifty years, and had taken about three drinks of whiskey daily for approximately the same period.

Examination was essentially negative, except for the condition of the extremities. The patient seemed well preserved for his age.

He was about 6 feet 2 inches in height, and weighed approximately 150 pounds. The systolic blood pressure was 120 and the diastolic 76. Both radial arteries pulsated normally but pulsations could not be felt in the ulnar arteries. Both femoral arteries pulsated normally. The pulsations in the right popliteal artery were reduced 50 per cent and pulsation could not be felt in the right dorsalis pedis or posterior tibial arteries. Pulsations could not be felt in the left popliteal, left dorsalis pedis and left posterior tibial arteries. The sclerosis in the peripheral arteries was graded 1. Examination of the urine was negative, except for a slight trace of albumin. The hemoglobin was 12.9 gm in each 100 cc by the acid-hematin method. The erythrocytes numbered 4,380,000 and the leukocytes, 9,300. The differential count showed lymphocytes 13, large mononuclear cells 2, transitional cells 7, and

FIG. 7. Cross section of a small arteriole. Marked cellular thickening of the intima is shown, which almost completely occludes the lumen (hematoxylin and eosin stain $\times 200$).

neutrophils 78 per cent The concentration of urea was 35 mg in 100 c c of blood, uric acid was 276 mg and sugar was 76 mg Roentgenograms of the feet and legs were negative The return of phenolsulphon-phthalein was 40 per cent in two hours The electrocardiographic report showed a rate of

86, auricular premature contractions, and aberrant QRS complex in derivations I and II, notched left ventricular preponderance, notched P wave in derivations I and II and inverted T wave in derivation III

The ulcer at the base of the left great toe gradually increased in size and on the fourth

FIG 8 Longitudinal sections of the left femoral and popliteal arteries showing the vessels occluded with an acute thrombus

day after admission the dorsum of the foot became gangrenous. There was also a distinct change in the patient's general condition. The left leg was amputated March 11, 1930, at the juncture of the upper and middle third of the femur. The femoral artery was thrombosed at the site of the amputation. The afternoon of the operation, abdominal distention developed, which could not be relieved either by gastric or colonic lavage. The distention and toxemia increased, the blood urea rose to 130 mg in 100 c.c. the following day, the patient's strength gradually failed, and he died forty-eight hours later, in spite of supportive measures.

At the bifurcation of the popliteal artery of the amputated leg, the vessel was occluded by an ancient and completely organized thrombus, about 1 cm in length. The remainder of the popliteal artery was occluded by a recent red, partially organized

thrombus. The posterior tibial artery was patent to the lower third of the leg. Below this level it was occluded by a partially organized thrombus (figures 1 and 2). Figures 1 and 2 should be compared with figure 3 which is the cross section of the posterior tibial artery of a subject with arteriosclerosis. The anterior tibial and dorsalis pedis arteries were occluded (figure 4) with an ancient organized thrombus. The deep veins were also involved in a similar occlusive process (figure 5). Many of the smaller arteries and arterioles showed active proliferation of intima (figures 6 and 7). At necropsy the left stump did not show evidence of infection, but the skin adjacent to the wound was dark red, indicating a poor blood supply. The left femoral artery (figure 8) was occluded with a recent red thrombus which extended up to Poupart's ligament. The iliac arteries were patent and did not show gross

FIG. 9. Cross section of the left external iliac artery. Thickening of the intima is shown (Van Gieson and eosin stain $\times 150$).

evidence of arteriosclerosis but it was shown to be present on microscopic examination (figure 9). The aorta was also patent and showed arteriosclerosis, graded 3 in the arch and upper thoracic portion, and graded 1 to 2 in the abdominal portion. In the abdominal aorta there was an area 3 by 3 cm which was covered with relatively soft necrotic material, it is possible that an embolus may have broken off and lodged in the left popliteal artery, serving as the basis for the propagating thrombus which had completely filled the left popliteal and left femoral arteries. Other significant observations were not made at post mortem examination, except the presence of chronic mitral endocarditis, chronic duodenal ulcer, and mild atrophy of the brain with arteriosclerosis, graded 3, of the arteries composing the circle of Willis. Peritonitis was not present. The heart weighed 429 gm and the coronary arteries showed arteriosclerotic changes, graded 2. The lungs showed evidence of congestion, but pneumonia was not present, either on gross or microscopic examination.

The long history (1903 to 1929) of symptoms in both hands and both feet, the occlusion of both ulnar arteries, the amputation of four toes at irregular intervals and the prolonged healing following, the absence of demonstrable calcification in the vessels by roentgen ray, and the appearance of the microscopic sections from the amputated leg, make the diagnosis of thrombo-angitis obliterans certain. The arteriosclerosis in this case was not more advanced than would be expected among men of that age, in fact, it was not as advanced as we have often noted in younger persons who were having few, if any, symptoms referable to the extremities. The extent of the acute thrombosis in the left femoral artery (the thrombus extended from the bifurcation of the popliteal to Poupert's ligament) makes it doubtful whether the stump would have healed owing to

the marked and sudden diminution in the blood supply to the extremity.

This case calls attention to the fact that age, of itself, does not eliminate thrombo-angitis obliterans. The pathologic changes in the vessels of the amputated leg indicated the presence of chronic inflammatory rather than a degenerative type of disease and proved the diagnosis of thrombo-angitis obliterans. No doubt an erroneous diagnosis of Raynaud's disease was made at the onset of symptoms, because of the color changes in the hands on exposure to cold. It should be emphasized again that the three-phase color reaction in men, when the hands and feet are exposed to cold, does not necessarily indicate Raynaud's disease, it usually indicates an early symptom of thrombo-angitis obliterans. For a period of years, there had been a succession of digital ulcers, and gangrene, with amputation and slow healing. At the patient's subsequent visits to the clinic in 1907 and 1915, the correct diagnosis was not made.

COMMENT

Three cases of thrombo-angitis obliterans in persons aged sixty-three, sixty-five and seventy-three years, respectively, are reported. One patient gave clinical evidence of having had the disease for more than twenty-six years, and another for more than thirty years.

A pathologically proved diagnosis was obtained in one case. One patient, a man aged seventy-three years, is the oldest subject we have seen with this disease, and so far as we are aware is the oldest on record.

The data concerning these patients give additional light on prognosis. The disease is characterized by a chronic relapsing lesion of the vessels, and occlusion and collateral circulation struggle for supremacy. The element of time is most important in this struggle, since on this, preservation of the part rests. If the intervals between relapses are short, and the time for adequate collateral circulation is brief, trophic changes and gangrene are likely to ensue. Conversely, if the intervals of time between relapses are long, collateral circulation becomes adequate and sufficient supply of blood to the distal areas is assured. The first consideration regarding prognosis is the frequency of the exacerbation of the disease. Our experience in a large

number of cases of thrombo-angitis obliterans shows clearly that a high percentage of bad prognoses (regarding amputation) is not justified in this disease. Probably 20 to 30 per cent of patients will lose one or more limbs. An increasing number of early diagnoses, the institution of protective and therapeutic measures, and the institution of protective types of operation, as sympathetic ganglionectomy in selected cases, are still further reducing this percentage. Increasing knowledge by the profession of the dangers of surgical tinkering with the affected digits in which the supply of blood is already diminished will perhaps accomplish greater changes in the prognosis than any other single factor.

Treatment of Angina Pectoris With a Tissue Vasodilator Extract—Preliminary Report*†

By JOSEPH B WOLFFE, M D, DONALD FINDLAY, Ph D, and
EDWARD DESSEN, M D, *Philadelphia, Pa*

IN 1926 E K Frey and H Kraut¹ found a substance in the urine which they demonstrated to have vasodilator properties, and which they believed to be a circulation hormone (Kreislaufhormon). In 1929 Frey² operated on a patient who had a pancreatic cyst and found that the cystic fluid was rich in this particular hormone. They have since studied this product extensively and have come to the following conclusions:

- 1 The hormone is present in the blood and is excreted in the urine
- 2 The hormone is present in the blood mainly in an inactivated form and excreted in the urine in its active state
- 3 The active hormone obtained from the urine can be rendered inert by the addition of blood serum
- 4 The inactivated hormone can be reactivated by the addition of acid or a certain vegetable enzyme, papain
- 5 The hormone is not histamine
- 6 The hormone is elaborated and stored mainly in the pancreas
- 7 The action of the hormone is to

cause a drop in blood pressure by means of vasodilation

- 8 The hormone can be used to advantage in patients suffering from angiospastic diseases, coronary sclerosis, and certain forms of hypertension

At the session of the Berliner Medizinische Gesellschaft, July 9, 1930, Frey³ discussed this newly discovered internal secretion and also reported the isolation and purification of a substance, a polypeptide, which inactivates it. "The relation of the link between the hormone and the inactivator is dependent upon the prevailing reaction in the tissues, so that a slight shifting towards the acid side produced by the appearance of acid metabolism releases the link between the hormone and the inactivator, whereby the vasodilator action comes into operation." In this alternation between union and releasing of the active substance—which is brought about by a slight change of the hydrogen ion concentration—Frey sees its real physiologic importance which in connection with internal secretion proves the substance to be a genuine hormone. He also reported the successful use of the hormone for the past two years. "The blood pressure in essential hypertension not caused by the kidneys drops considerably and remains at a lower level after the injections are discontinued. In

angina pectoris and especially in intermittent claudication the attacks subside. Amputations that in necrosis and gangrene of the extremities would otherwise have been necessary, were avoided, owing to the action of the remedy."

P. Gley and N. Kisthinos⁴, in 1929, prepared a substance from the pancreas which is apparently the same as the one described by Frey and Kraut. They found that the extract had vasodilator properties, was free of insulin in the animal under experimentation, antagonized the action of epinephrine, and caused a transitory hypotension that was not due to choline, histamine, or peptones. H. Vaquez, R. Giroux and N. Kisthinos⁵ have used the product clinically in the treatment of angina pectoris and have reported the most remarkable results. They treated twenty patients in various stages of angina, and in practically every case succeeded in obtaining almost complete symptomatic relief.

Recently J. S. Schwartzman⁶ reported the results of using a voluntary muscle extract in cases of angina pectoris. He explains the favorable effects that he obtained by the presence in the muscle extract of a substance that acts as an antispasmodic, the substance being liberated in a muscle during exercise. M. S. Schwartzman⁷ used the preparation in cases of angina pectoris and also reports very gratifying results. In reference to the antispasmodic substance being found in voluntary muscle only, K. Fahrenkamp and H. Schneider⁸ this past year made a comparative study on man of two extracts, one from skeletal muscle, the other from heart muscle; this latter was previously believed by Haberlandt

to represent a true heart hormone. They found that the effects of the two were identical. Administered either orally or intravenously each of these extracts completely controlled attacks of angina pectoris. The authors concluded that the heart muscle extract does not represent a true heart hormone.

These findings add significance to the work of A. M. Drury and A. Szent Gyorgi⁹. They studied the effect on the heart of simple extracts of heart muscle, and of other body tissues. Some of their conclusions were as follows:

- 1 Simple extracts of heart muscle, brain, kidney and spleen have a definite and transient effect upon the mammalian heart.
- 2 The substance responsible for this action has been isolated and appears from its chemical properties to be adenylic acid. Its activity apparently depends upon the ease with which the substance is deaminated in the body.
- 3 Adenosine, prepared from yeast nucleic acid, had an action identical to adenylic acid.
- 4 The physiological activity of both substances has been tested by intravenous injection into the whole animal.
- 5 Among other effects upon the heart, they slow the rate, impair conduction from auricle to ventricle and arrest experimentally produced auricular fibrillation. They shorten the absolute refractory period of an improved slowed conduction in the auricle due to high rates of beating.
- 6 They lower general arterial pressure. This is due in part to the cardiac slowing and in part

to a general arterial dilatation
They dilate the coronary vessels
and inhibit intestinal movements

We believe that all these substances mentioned are identical, as borne out by our studies, and we are at present making further investigations to prove this

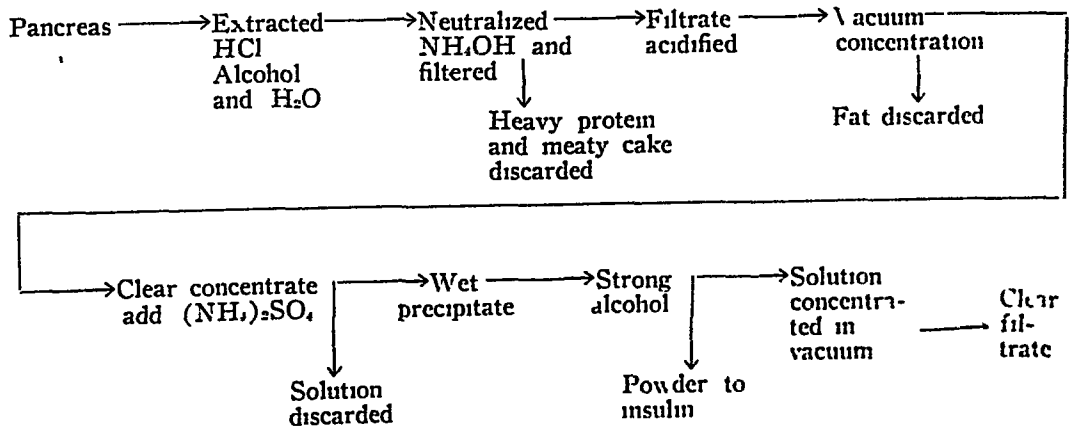

After considering all the experimental and clinical data on the subject, as well as our own work, it seems to us that we are dealing here with an active principle that is either adenylic acid or adenosine. In this connection we want to take cognizance of the editorial in the Journal of the American Medical Association of October 11, 1930. The editor there inclines to the belief that the so-called heart hormone can be obtained in any body tissue and is most likely histamine. While we do not believe that the substance in question is a specific heart hormone, and although it is true that it can be obtained from various body tissues, it nevertheless has definite primary vasodilator properties. It is not histamine as the editor infers. Of this we are quite certain.

We became interested in this product since it is an adjunct in the treat-

ment of angina pectoris and other vascular diseases. We prepared an extract in a manner similar to the method of P. Gley and N. Kisthinos¹⁰. The ground pancreas was extracted with a menstruum of alcohol and water, so that the final alcoholometer reading was 63 per cent. Sufficient hydrochloric acid was used to yield a pH of 2.4. This mixture was run through a colloid mill for thorough extraction. The product was neutralized with ammonia and filtered. This filtrate, acidified with sulphuric acid, was concentrated under vacuum and the clear concentrate sulphated, using ammonium sulphate to one-half saturation. The wet precipitate treated with strong alcohol yielded a powder containing insulin and a 90 per cent alcoholic liquor. This liquor contained alcoholic extractions of the precipitate and the mother liquor wetting it. It was concentrated with the addition of water.

The clear filtrate obtained in the above manner was used for purposes of injection. In making a preparation for oral administration at stage eight, instead of sulphating and collecting the insulin, the product was alcoholized to ninety per cent and then concentrated

FIG 4 Electrocardiographic tracing of rooster, showing cardiac slowing following injection of vasodilator extract

In order to make sure that the ammonium sulphate used in the process had no hypotensive effect, we administered 0.1 cc of 5 per cent ammonium sulphate. No drop in tension followed.

To rule out the possibility that insulin was responsible for the pharmacologic effect, an injection of 0.75 cc of insulin (20 units) was given. This also failed to cause any appreciable change in blood pressure. To make certain that the animal was still responding, the experiment was concluded with another injection of the vasodilator extract. The result was

similar to the first response, a drop in tension occurring.

We then proceeded to use this vasodilator extract by intramuscular injection.

PREPARATION USED

The extract* which we used, prepared in the above described manner contained 15 hypotensive units per cc. A hypotensive unit according to the method of standardization of P. Gley and N. Kisthimos¹⁰ is that amount of the extract which when suddenly in-

Our investigation as to the possibility of an anaphylactic action due to the protein that the substance might contain also gave negative results.

SELECTION OF CLINICAL CASES

The cases selected for trial for the purpose had suffered from angina pectoris for a number of years and had failed to respond to all forms of treatment. Nitroglycerin afforded a temporary relief during an attack but did not prevent the recurrence of the attacks. Some were from the University Hospital, Wilkes-Barre, Pa., and some from our private practice. In every case the patient was under the care of a physician.

Observations were under our own personal supervision. Subjects who had experienced a recent coronary occlusion were rejected. Electrocardiograms and teleroentgenograms were obtained in every case. The whole series had negative blood Wassermanns and negligible urinary findings. Blood pressures were normal in 8 cases and elevated in 12. Cardiac enlargement was present in 14 cases and electrocardiograms showed inverted waves suggestive of supposed coronary disease in 7 cases. Two showed coronal waves during an attack, and two others who had normal electrocardiograms during the beginning of the treatment showed so-called coronary waves.

3	350	0	Vasodilator extract 1 1000	1 c c	
		II	Intraperitoneally Intraperitoneally	10 c c undi- luted pancreas extract	Injected 1 49 P M No reaction the animal remained quiet during many hours of observation

ing the time they were receiving the injections. Four of the group had an increased blood pressure during an attack. Three of the patients with a normal pressure at the time of the study were known to have had hypertension at some previous time.

METHOD OF TREATMENT

The method of treatment consisted of daily intramuscular injections, the dosage varying from a minimum of 60 units (4 c c) to a maximum of 150 units (10 c c). The usual dose was 75 units. Where treatment was temporarily stopped the interval before resumption was never more than a week. Every case had been receiving theobromine sodium salicylate, grs 5, acetylsalicylic acid, grs 5, and pheno-

barbital, grs $\frac{1}{4}$, before the injections were started, with some slight favorable effect. This medication was not discontinued when the vasodilator extract therapy was begun. A dose of oleum ricini, 2 oz, was given once every two weeks. Smoking in any form was absolutely forbidden. Instructions were given as to diet and time of meals to avoid any discomfort incident to flatulence. Care was taken to have the patients avoid over-exertion or over-excitement, in other words, we were particular to safeguard against apparently minor disturbing influences.

RESULTS

There was a cessation of the anginal attacks in 11 of the 20 cases. Six others experienced some relief, but

[illegible]

still complained of occasional mild paroxysms. In 3 cases the result was a failure.

The following case history is illustrative of the group who were relieved of their anginal attacks.

Case 5 M. C., age 50, salesman. The patient was first seen in 1928. He complained of attacks of substernal pain radiating to the throat and left arm. The attacks were precipitated by excitement or exertion and lasted from three to ten minutes. They were occurring about once in two weeks. Although he complained of dyspnea after an attack he never suffered from any respiratory embarrassment at any other time. Upon physical examination we found his heart to be of normal size, the heart muscle tone somewhat muffled, the rhythm and rate were normal. There was a systolic roughening over the aortic area. Blood pressure 180 over 95.

The electrocardiogram revealed the QRS complexes to be of rather low amplitude (figure 7), but otherwise showed no abnormality. The teleroentgenogram showed

the cardiac silhouette to be normal, but the aortic arch was slightly widened and deflected upward and to the left.

The patient was given a combination of theobromine, acetylsalicylic acid, luminal, nitroglycerin, and codeine sulphate. He felt somewhat better but he had two severe attacks at the end of the month. He was then admitted to the hospital where he was given a course of Nauheim baths and injections of sodium citrate. He improved very much in the hospital and after his discharge he had only a few minor attacks until April, 1929. However, tracings taken at intervals showed progressive cardiac damage.

In April the patient suffered several severe attacks of angina and was again admitted to the hospital for a similar course of treatment. This time he felt fairly well until January, 1930. He then had several severe attacks and morphine had to be resorted to. Hitherto nitroglycerin had been effective in controlling the painful crises. The attacks now occurred several times daily. After a week of palliative measures without relief we commenced to give him injections of vasodilator extract, 60 units daily, for twelve

days He had no attacks while taking the injections The following week he had a minor attack We then gave him another series of injections, 75 units daily for twelve days He has had no attacks to date He received no more injections but he has taken 60 units by mouth daily since

The following patient also responded very gratifyingly to the vasodilator extract

Case 16, M L, Age 51, machine operator He had been suffering from the subjective symptoms of high blood pressure for three years He was admitted to the hospital in September, 1929, for this condition After being there but a few days he was seized with an attack of excruciating pain over the precordium which left him with a burning substernal sensation He then claimed that he had occasionally experienced similar attacks but much milder in character for over a year His blood pressure ranged between 157 to 200 systolic and 90 to 110 diastolic Teleroentgenogram of the heart showed it to be generally hypertrophied with slight widening of the aorta The patient was in the hospital for three months during which time he had several severe attacks and many minor ones We began giving him the vasodilator extract by injection February 15, 1930, until he had received about 3600 units He has been free from attacks since.

The next history is that of a patient with coronary occlusion whom we succeeded in relieving of her pain, but who died six months after we had ceased treating her

Case 9, G H, age 53, housewife The patient first came under our observation in January, 1928, with a history of a few years' duration, of attacks of precordial pain radiating to both shoulders and to the left arm She also complained of constant headaches and dizzy spells Her blood pressure was 225 over 90 She was sent to the hospital Her teleroentgenogram revealed the heart to be enlarged in its transverse diameter and the aorta to be widened She felt better after a three months' stay in the hospital and a similar period of convalescence at a seaside resort However, as soon

as she returned to her home she began to have attacks Two months later she was hospitalized again

On March 1, 1930, she began to receive daily injections of the vasodilator extract She received in all 2700 units and ceased to have even the slightest attacks She felt so well that she failed to report for observation at appointed times A short time ago we were called to see her and found her moribund from what appeared to be a coronary occlusion A few days later she died

The following is a case of the type that we grouped as being partially relieved

Case 13, A M, age 62, bookkeeper The patient dated her illness to November, 1928, when she suddenly experienced a severe cramp in the epigastrium while walking She was immediately rushed to the hospital where she was treated for acute indigestion At this time it was discovered that she had hypertension and therefore she remained under medical supervision When we saw her she complained also of a sensation of weakness around the heart, dyspnea, and palpitation, and, on excessive exertion, of occasional attacks of excruciating pain in the left shoulder, which would leave her very weak These shoulder pains would be relieved by a hot water bag over the precordium or by drinking hot water In February, 1930, we had her admitted to the hospital for treatment Teleroentgenograms showed the heart to be enlarged in its transverse diameter, and the descending arch of the aorta to be prominent Her blood pressure was 170 over 85

Commencing February 3, 1930, she was given daily injections intramuscularly of vasodilator extract She had one attack after the fourth injection which she claimed was the worst she ever had As a matter of fact we had some difficulty in convincing her to continue with the injections The attack was relieved by 1/100 gr of nitroglycerin She remained in the hospital for two months during which time she received a total of 1600 units During this time she was receiving also theobromine, luminal, and acetylsalicylic acid, and a dose of castor oil every other week We last heard of her

in September, 1930. She claimed that she had been subject to attacks of palpitation and cardiac discomfort, which according to her history seemed to be due to premature beats. She had suffered no definite anginal attacks. Physical examination revealed no change.

The course of events in one of the cases in which the result was a failure, was as follows:

Case 2, S. K., age 63, had not worked for four years due to poor health. The patient was first seen in December, 1929. He was suffering from severe attacks of precordial pain and a strangling sensation, with the radiation of the pain to both shoulders and arms. The patient was extremely ill with marked signs of congestive cardiac failure, and his skin was cold and clammy. He appeared to be much older than his stated age. His blood pressure was 120 over 80. He had been suffering from these attacks for the past eight months but in the last two months they had become progressively worse, until they were unbearable. His doctor had to resort to morphine for the last month in order to give him relief. He was removed to the hospital for six weeks and was given a course of Naphthol baths. The teleroentgenogram showed his heart to be enlarged and the transverse diameter and the aorta to be enlarged.

While in the hospital he did very well, requiring only one hypodermic of morphine during his stay. Until the time of discharge he felt better, but when he went home he commenced to have attacks again.

On February 2, 1930, he began to receive the extract of vasodilator extract, 1629 extract, B. He had no relief during this time, but he developed congestive cardiac failure, which could not be checked in spite of digitalis. Morphine had to be resorted to for relief of pain and cardiac failure.

Summary

The results of the treatment of our cases were as follows:—In the majority of cases relief has been obtained, and in some cases the patients have been cured. In some cases the results have been temporary, and in some cases the results have been permanent.

ly relieved. Failure was met with in 15 per cent of the cases. Most patients developed "coronary" "T" waves at the same time that they improved symptomatically (Figures 7 and 8). One patient who suffered from severe intermittent claudication in addition to angina and had been advised to have a sympathectomy performed for the former, was relieved of both complaints by antisymphathone. The four patients who had a rise of blood pressure during an attack were all relieved. Two of the three patients who failed to respond were decompensated at the time treatment was administered. Hence they can be regarded as unfit for trial, since Vaquez also points out the certainty of failure if treatment is undertaken in such instances.

COMMENT

It is our belief that antisymphathone is a valuable addition to the therapeutic armamentarium against angina pectoris. This dread syndrome has long stood invulnerable in very many instances to all methods of treatment. What occasional good results we have hitherto obtained that were more than merely temporary, could never be entirely ascribed to any one drug or therapy. The use of the vasodilator extract promises much better results. To say that it will permanently relieve every case of angina pectoris is to assert a belief that is not warranted by the character of our results or the time that they have endured. But to conclude that it will at least produce some relief in half of the cases is not a conservative estimate of what can be hoped for. However, we do not believe that the vasodilator therapy is

L K 4/14/30

10/1/30

10/20/30

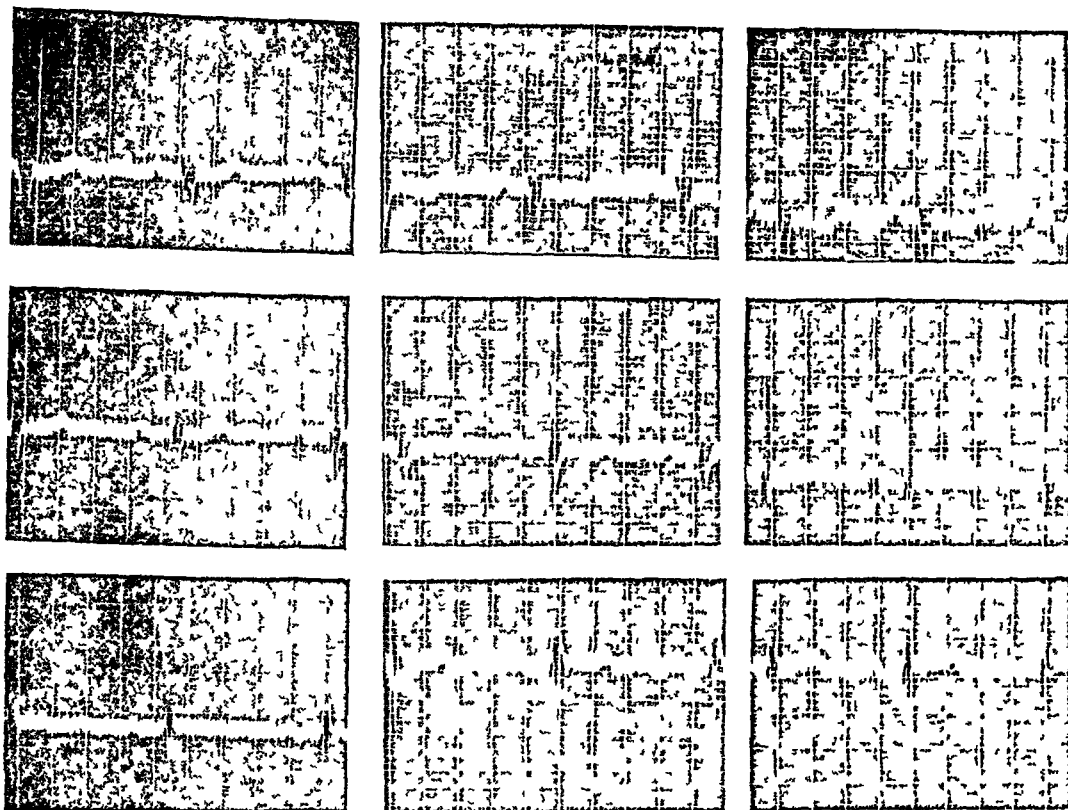

FIG 8—Electrocardiograph, Case XV, showing development of coronary T wave during treatment

the lesions underlying the anginal attacks. As noted above, one of our patients completely freed of painful crises, experienced a coronary occlusion that was fatal, two others developed coronary "T" waves while under treatment (figures 7 and 8)

A few words at this time as to the *modus operandi* of the extract in relieving angina pectoris would not be amiss. It was the feeling of the French investigators that the beneficial results were due to a trophic action of the extract on the vascular system entirely separate from its hypotensive effects. Several of these patients had no hypertension to begin with and were benefited and several others continued to suffer although their tension was

lowered. We have treated some patients suffering from obliterative arterial diseases of the extremities with this substance and observed improvement. Patients who suffered from intermittent claudication have been greatly benefited by the use of this extract.

Frey's opinion was that all therapeutic benefits derived from the use of the circulation hormone were attributable to its vasodilator action. He mentions good results which he obtained in various angiospastic diseases, coronary sclerosis and hypertension. H. Schauder¹² recently reported the case of a patient who for more than a year had suffered from severe intermittent claudication and arteriosclerosis of the extremities which resisted all therapy.

COMMENT

It is our belief that antisymphathone is a valuable addition to the therapeutic armamentarium against angina pectoris. This dread syndrome has long stood invulnerable in very many instances to all methods of treatment. What occasional good results we have hitherto obtained that were more than merely temporary, could never be entirely ascribed to any one drug or therapy. The use of the vasodilator extract promises much better results. To say that it will permanently relieve every case of angina pectoris is to assert a belief that is not warranted by the character of our results or the time that they have endured. But to conclude that it will at least produce a remission in half of the cases is only a conservative estimate of what we have found. However, we do not believe that the vasodilator therapy removes

change
The course of events in one of the cases in which the result was a failure, was as follows

in September, 1930. She claimed that she had been subject to attacks of palpitation and cardiac discomfort, which according to her history seemed to be due to premature beats. She had suffered no definite anginal attacks. Physical examination revealed no

Case 2, S. K., age 63, had not worked for

four years due to poor health. The patient was first seen in December, 1929. He was suffering from severe attacks of precordial pain and a strangling sensation, with the radiation of the pain to both shoulders and arms. The patient was extremely ill with marked signs of congestive cardiac failure, and his skin was cold and clammy. He appeared to be much older than his stated age. His blood pressure was 120 over 80. He had been suffering from these attacks for the past eight months but in the last two months they had become progressively worse, until they were unbearable. His doctor had to resort to morphine for the last month in order to give him relief. He was removed to the hospital for six weeks and was given a course of Nauehm baths. The teleocent-
genogram showed his heart to be enlarged in its transverse diameter and the aorta to be widened

While in the hospital he did very well, requiring only one hypodermic of morphine during his stay. Until the time of discharge he felt better, but when he went home he commenced to have attacks again. On February 3, 1930, he began to receive the injections of vasodilator extract, 1620 units in all. He had no relief during this time and soon developed congestive cardiac failure which could not be checked in spite of stimulation. Morphine had to be resorted to and he died of progressive cardiac failure.

SUMMARY

Thus in 55 per cent of our cases we were able to obtain clinical relief by the use of the tissue extract for which we propose the name "antisymphathone". Thirty per cent were partial-

Treated with Frey and Kraut's circulation hormone the symptoms disappeared almost completely and the good results have persisted for thirteen months

The extract unquestionably has vasodilator properties. Work done on the dog leads us to believe that in this animal at least the primary fall in pressure is followed by a secondary rise. We are at present engaged in testing it on a large group of cases suffering from Buerger's disease and other forms of arterial disease, to determine its clinical applicability. However, it is our belief that the action of the vasodilator extract in relieving angina is associated with its adrenalin neutralizing properties. While the extent of our research on this score only permits us to speculate about it at this time, there are several thoughts that we would like to emphasize.

Sometime ago Levine, Ernstene, and Jacobson¹² showed that an anginal attack could be induced in almost every instance in patients suffering from angina pectoris by the subcutaneous injection of 1 cc of 1 to 1000 epinephrine solution. Control subjects did not experience that reaction.

Loewi¹³ as far back as 1908, experimenting on animals, concluded that the pancreas through an internal secretion (now known to be insulin) furnished a chemical substance which is a depressor or inhibitor of the sympathetic nervous system. The effects of adrenalin, which is a sympathetic excitant, were antagonized or lost. Loewi tried to form a clinical test for pancreatic function from these conclusions, using the reaction of the iris to adrenalin as an index. The applicability and fate

of this test which bears his name is not our concern at this time. The thought that we would like to bring out is that if adrenalin injected into certain patients subject to angina will produce an attack, and if a certain vasodilator obtained from the pancreas moderates the action of adrenalin, a possible explanation of the favorable action of pancreatic extract in relieving angina lies in this very neutralizing property. In other words, antisymphathone acts in the same manner as a sympathectomy. However, some cases of angina pectoris seem to be associated with a preponderance of so-called parasympathetic influences on the heart and other viscera over sympathetic influences. In these cases the use of antisymphathone must be strenuously avoided.

Of course Levine's work does not prove that anginal attacks as they occur in ordinary life are caused by an influx of adrenalin to the circulation. But the frequency of the paroxysms following effort, fright, et cetera, and the common, if not constant observation of the increase in blood pressure during an attack, could readily be explained by an increased adrenalin output in a patient with a damaged cardiovascular system. In fact, as we have just stated, in some cases of angina pectoris parasympathetic influences seem to be predominant.

Whether the injections of antisymphathone stimulate further production of its active principle in the pancreas, or whether the extract acts as a buffer against adrenalin in direct proportion to the amount injected, and whether there is an associated pancreatic disease or deficiency in patients suffering from angina, are questions

that all may be properly asked at this point. Much work and research are necessary before they can be answered, and it is our hope that we have afforded some stimulus to thought and investigation in this direction.

Our purpose in bringing this product to the attention of the profession without any delay is to promote its wide clinical trial. Our work has been far from conclusive. The impossibility of the expression of the locality of pain by animals in the laboratory leaves only the human organism as the means of evaluating the efficacy of the drug. The preparation can be used without further study because of its lack of toxicity. We have administered more than 5000 injections and there has never been any untoward local or general reaction, save a slight burning at the time of injection. It should not, however, be used in cases with parasympathetic preponderance.

Owing to the woeful lack of other than temporary palliatives for anginal crises, we felt assured that the advent of the extract would be welcomed. Our only fear is that the drug may be used with too much enthusiasm and eagerness to allow a proper appraisal of its therapeutic value. It always has been a clinical observation of ours that one's attitude in employing a new therapeutic measure somehow was sensed by the patient and reflected in his or her

reaction. We tried studiously to avoid showing our mental attitude in the hope that where the only measure of our results was the patient's own estimate of his condition, we did nothing consciously to prejudice it.

CONCLUSIONS

1 Twenty cases of angina pectoris were treated with tissue extract (anti-sympathone).

2 Symptomatic relief was obtained in eleven cases, six had partial relief, and three had no relief.

3 We believe that the extract is a valuable addition to the therapeutic armamentarium against angina pectoris, to be used in conjunction with all other means at our command.

4 We believe the mode of action is by sympathetic depression. It should not be used in cases with parasympathetic preponderance.

5 The preparation is non-toxic, its only contraindication being acute coronary thrombosis and the parasympathetic group of cases.

6 We urge wide clinical trial of the extract to better determine its exact value.

Note: We desire to express our indebtedness to Dr. Marie Severac, Mr. R. H. Hutchison, Mr. Arnold Quici, and Mrs. Lena Sklar for their valuable aid in certain phases of this work.

Medulloblastoma Cerebelli*†

A Case with Autopsy: Midline Cerebellar Tumors in Children and Young Adults

By KARL ROTHSCHILD, M D, *New Brunswick, N J*

BRAIN tumors and especially cerebellar tumors are so frequently seen—and so frequently overlooked—that it seems justifiable to publish a report of some unusual findings in a journal read by the internist. The present paper intends to deal with one phase of the problem, the cerebellar tumors of children and young adults.

In 1925, Bailey and Cushing¹ published an extensive study of these tumors. They report that the initial symptoms were those of increased intracranial tension of abrupt onset, starting only a few months before admission to the hospital. Only occasionally headache was present, usually attributed to some gastric upset. As further symptoms they mention rapid appearance of choked disk, separation of cranial sutures (figures 2 and 3), history of staggering gait, ataxia, more in the lower extremities than in the upper; in a few cases cerebellar seizures with signs suggestive of basilar meningitis. Nystagmus was inconspicuous, diplopia often present, sometimes bilateral abducens palsy. Most cases occurred below the age of

fifteen years. At that time the authors stated that attempts to extirpate these tumors in toto were futile and even exposure and decompression were accompanied by high mortality. "Conservative attitude is a course of wisdom." They recommend decompression followed by persistent roentgen-ray therapy. In 1927 Cushing² reports eleven cerebellar tumors of which the "majority have been median gliomas of one variety or another originating from the roof of the fourth ventricle. Seven of them had a good prognosis." He reports the finding of an enlarged head with MacEwen's sign, the enlargement of the head being followed by cessation of headache and subjective freedom from discomfort but often by that time the vision began to fail. In closing his article he states "Medulloblastoma of the cerebellum is so common a lesion in preadolescence that when a child has unexplained vomiting enlargement of its head and gives a story of periodical unsteadiness look at the eye grounds every week or two." Articles by Olivecrona and Lyschalm and by Bailey, Sosman and van Dessel published in 1926 and 1928, show that the growth of the tumors may be inhibited for a time by roentgen therapy but that the outcome has been fatal in every case.

*From the Department of Neuro-Psychiatry, St Peter's General Hospital New Brunswick, N J

†Received for publication March 31, 1931

Bailey⁵ in his latest article (1930) inquires into the causes of these failures. He rejects the idea that the neoplastic cells may have become radio-resistant. He rather believes that the patients may have received too much roentgen ray treatment. As the method of probable choice he now recommends decompression and thorough radiation of the entire cerebrospinal axis.

Case I The following is a case report of a child, John K., six years of age, who was admitted to my service at St. Peter's General Hospital on May 14, 1930.

Family history Nothing unusual.

Personal history Had chicken-pox at the age of six months, pneumonia at the age of two years, whooping-cough at the age of five years.

Present history Four months before admission the patient fell while skating and struck his head on the ice. He got up and walked home. One week later, he complained of pain in the occipital region of the head and in the abdomen and was taken to see several physicians. Several x-ray pictures were taken and there was a long argument whether a line seen in one of the pictures represented a fracture or not.

About four weeks before admission, the boy complained of dimness of vision, and gradually became blind. On the day of admission, he was seen by Dr. Forney of Milltown, who referred him to my service.

Physical examination A white boy, six years of age, well developed and well nourished, complaining of abdominal pain and apparently blind.

Head and neck Head very large. Veins somewhat large and tortuous. Both pupils were enlarged, round and equal. Right pupil reacted very faintly to light, while left did not react directly, but did so when light was thrown into the right pupil. There was a very slight stiffness of the neck.

Chest Thorax of good capacity, good expansion. Apex beat in 5th interspace, one-half finger breadth within nipple line. Sounds normal, no murmurs. Breath sounds vesicular.

Abdomen Slightly distended, no tenderness, no masses felt.

Extremities Good physical power.

Neurological examination Reflexes.

Tendon reflexes of legs and arms were equal and normal. For a child, they might even be considered below normal. In fact, it was difficult to elicit the arm reflexes at all. Abdominal reflexes were absent. There was an indication of a slight Babinsky's sign on the right side, but nothing definite. There was a suggestion of a bilateral Kernig's sign. There was no ataxia. Finger-finger and finger-nose tests were performed well. The child walked in a straight direction. There was no nystagmus. There were no disturbances of any cranial nerves, except the optic.

Ophthalmoscopic examination Marked optic neuritis in both eyes, with signs of atrophy on the left side. There were many minute ruptures in the retina, showing the sclera, possibly due to suddenly increased pressure. There was also marked choroiditis of the subacute type. The right side was completely blind. The child, however, could notice a flash-light at a distance of four inches with the left eye.

Laboratory findings Hemoglobin, 80%, leukocytes, 9,100, erythrocytes, 4,200,000. Polynuclears, 67%, small lymphocytes, 29%, large lymphocytes, 4%.

Diagnosis In view of the amaurosis, the papilledema, and lack of other localizing symptoms, we made a diagnosis of tumor in the midline of the posterior fossa, probably of the cerebellum.

Progress notes As the child had been in the condition in which he was brought in, for several weeks, there was no indication for hurried therapeutics, so a roentgenogram was ordered to be taken next morning, and dependent on the picture, we considered the possibility of doing a cisternal puncture.

In the morning, the child became rather restless, was crying, and it was impossible to take the roentgenograph. While I was seeing another patient in the children's ward, I was called to see the boy, who had been stricken suddenly by a seizure of not very definite symptomatology. There was frothing at the mouth, incontinence of the rectum,

slight deviation of the eyes to the left, and of the head to the right, absence of reaction of the pupils which were equal and myotic, marked cyanosis of ears and fingers

Heart sounds were irregular and faint, respiration was irregular, of a staccato type, about six per minute

It was deemed advisable to do a spinal puncture. We obtained a clear fluid, under about 12 mm pressure. We removed 1 cc, and the pressure dropped to 7 mm. Cyanosis disappeared, the heart sounds became regular and louder. The respiration, however, did not improve. Withdrawal of 2 cc more, did not help the respiration. 1/20 gr of alphalobelin did not stimulate the respiratory center. The respiration became slower, and ceased entirely within 3 minutes. A cisternal puncture done immediately after death showed fluid of rather viscous consistency, under normal pressure. Immediately after death, we viewed the eye grounds again, and the right eye appeared as before. In the left eye, however, the atrophy of the disks could not be seen so well, because there were acute neuritic changes, with tortuosity of the blood vessels.

Autopsy An autopsy was performed by me with the assistance of Dr Candella. The body was that of a male child of 6 years, well-built and well-nourished, without signs of degeneration or deficiency.

The head appeared much larger than the average, in fact, it was as large as an average adult's head. The circumference was 24½ cm in the longest diameter.

The scalp was removed in the usual way. On removing the skull, it was noticed that the sutures were widened to about 6 mm. Between these sutures, there were two different layers of bone, filling the gaps. It appeared that these insertions had been produced at different times.

The inner aspect of the bone showed many impressions, in fact, there was a true picture of the external architecture of the brain impressed on the bone (convolutional atrophy). Dura was removed easily. Pacchioni's granulations were normal in number, but enlarged. The sinuses within the dura were widened. There were no signs of old or recent infections of the arachnoid or pia membranes.

The brain was removed in toto, by a section which included as much of the oblongate medulla as possible. The weight of the brain was 1425 gms. The external appearance of the brain was normal. Both halves were equal in size. The cerebellum appeared slightly sub-normal in size, but its two halves were equal, and it felt soft throughout. The origins of the cerebral nerves were unobstructed. There was no pathology of the optic tracts. The oblongate medulla showed

FIG 1 Medulloblastoma of cerebellum. Note position in midline. Hemispheres are intact. No localizing symptoms. Natural size.

normal contour and architecture on transverse section

The cortex appeared rather thin. The whole brain had a certain spongy appearance. The usual blood spots seen throughout the white substance were enlarged. The 3rd and 4th ventricles were markedly dilated, especially the 4th. The regions of the striate system and the internal capsule showed normal and regular formations.

On sectioning the cerebellum, a tumor (figure 1) was found of the size of a small hen's egg, originating from the roof of the fourth ventricle. It did not invade the hemispheres of the cerebellum, but only pushed them aside, and the impressions of the tumor were shown on the median aspects of the hemispheres.

The tumor had a spongy appearance, and there were several blood clots found in its interior, apparently originating from a very recent hemorrhage. Histological examination of the tumor proved it to be extremely cellular, without definite arrangement of the cells. In some areas there was pseudo-

rosette formation around a vessel. Mitoses were occasionally seen. There was a scarcity of stroma. The vessels showed proliferative endarteritis. These findings, together with the origin of the tumor from the roof of the fourth ventricle, permitted the diagnosis of a medulloblastoma (figure 4). The tumor was derived from medulloblasts, very young bipotential cells, both spongioblasts and neuroblasts having been found throughout the tumor. (I am indebted to Dr B J Alpers of Philadelphia for looking over the slides and preparing the photomicrograph.)

This case was extremely interesting because there were actually no physical or neurological signs present, except enlargement of the head and slowly increasing amaurosis, the reason being that the hemispheres were not invaded but only pushed aside but well preserved in their outline, as may be well seen in figure 1. This pathology would well corroborate Cushing's description

FIG 2. Roentgenograph of skull. Arrows point to places of secondary widening of sutures. Note impressions of brain on skull.

of these tumors. If the eye grounds of the child had been examined, the outcome might have been a different one. The law of *post hoc, ergo propter hoc*, certainly led the roentgenologist into over-emphasizing the value of finding a probable fracture. This child showed even fewer symptoms than are generally the rule inasmuch as there were not even vomiting or ataxia

present. Increasing blindness and abdominal pain were the outstanding symptoms. What really caused the unexpected death of the child a few hours after admission to the hospital is not definitely explained. We may assume that there was a sudden hemorrhage into the tumor.

Case II While writing this article I had admitted to my service another child, a boy ten years of age who fell sick with vomiting

FIG. 3. Antero-posterior view of figure 2.

and dizziness seventeen days ago. On admission to the hospital he showed choked disks and a slight horizontal nystagmus when looking to the right. He felt well while lying down. The deep reflexes were abolished, with possible presence of diminished left Achilles reflex and an indication of positive Babinsky's sign on the left. Finger-finger, finger-nose, and heel-knee tests were normal. Romberg's sign was positive. When sitting up, the patient became very dizzy and vomited. In this case also, I made a diagnosis of a tumor in the posterior fossa, invading the left hemisphere.

A few days after admission, the child felt considerably better, and was able to stand up and walk. He remained free from dizziness and headache. Only the choked disks remained unchanged. But after five days more, the former symptoms returned, the vision became dim and diplopia developed. The family physician later told me that

there had been diplopia for two days prior to admission to the hospital.

We now had the child admitted to the neuro-surgical department of the University of Pennsylvania. Dr. Charles H. Frazier kindly reported to me that he performed the operation, after having made a diagnosis of lesion of the posterior fossa, probably involving the left cerebellar hemisphere. The operation was performed under colonic and avertin anesthesia. The posterior horn of the left ventricle was tapped and a large quantity of fluid escaped. After transverse incision, the occipital sinus was ligated. The various surfaces of the left cerebellar hemisphere were explored with negative results. No difference in size of the hemisphere was noted and no displacement of the midline. An exploratory canula was introduced into the left hemisphere with negative results.

"For these several reasons, chiefly because of the lack of displacement of the midline,

FIG. 4. Microphotograph of tumor (Case 1). Extremely cellular. Tendency to grouping of cells around blood vessels. Occasional mitoses in nuclei. Stroma sparse. (Medulloblastoma)

because the two hemispheres were of equal size, because of the extensive amount of fluid in the subarachnoid space and in the ventricles, I was disposed to regard the case as one of pseudo-tumor. It is possible, I suppose, that there may be a neoplasm of the fourth ventricle but the evidence did not seem sufficient to warrant incision of the vermis" (Dr Frazier)

To judge from the history of the case, the free interval after an acute attack and the appearance of the roentgen plates, I am rather inclined to believe that we are dealing with a tumor. The description of Case I shows that there was in this case also no displacement of the midline, that the hemispheres were equal in size and that there was no evidence to touch of the presence of a tumor. Further developments will clear up this case. What is important from the standpoint of this paper, however, is that the diagnosis of a tumor (or a pseudo-tumor) over the original one of encephalitis was the point which decided whether this child should become blind or not. In either case, the diagnosis of involvement of the posterior fossa (by tumor or localized arachnitis) could be made from not much more than an eye ground examination.

Case III A similar case came under my observation on April 5, 1930. The patient, Norman R., a clerk of 24 years of age, had fainted while walking in the street, had fallen, and was taken to St Peter's Hospital. After admission, he vomited for several hours. The history dates back four years. Similar fainting spells had occurred every few months, each time while the patient was taking a walk. All attacks were accompanied by vomiting. A day or two after each attack the patient felt well again.

Neurological examination showed slight exaggeration of left biceps and triceps and absence of left abdominal reflexes. No a-

taxia of upper extremities. Tendency to sway toward the left when walking. Slight weakness of the left abducens. Eye grounds showed dilatation of blood vessels and choking of the disks, a little more marked on the left.

Diagnosis Cerebellar tumor (in midline)

In this case, also, the patient improved within a few days and left the hospital in apparently good condition. I saw him four months later and he was feeling well. He refuses to be examined again, for fear, apparently, that our original diagnosis might be verified.

All of these cases had been treated before, and diagnosed as fracture of the skull (case I), encephalitis (case II) and gastric upset (case III). Judging from these experiences, it may be well to follow Cushing's advice and in cases of recurrent vomiting and dizziness, examine the eye grounds every week or two.

The material described in this paper was presented at the Scientific Exhibit of the American Medical Association at the Philadelphia session, June 1931.

References 6 to 14 represent the latest investigations on the subject.

CONCLUSIONS

1 Tumors of the cerebellum, especially medulloblastomata, are found relatively frequently in children and young adults.

2 The onset of the symptoms of medulloblastoma in this region is so insidious, and the symptoms themselves are so slightly specific that the practitioner should be directed toward considering such a tumor in cases of dizziness and vomiting of indefinite origin. Choked disks are an early sign.

3 Three cases are described, one with report of autopsy.

Electrocardiographic Studies of the Effects of Propylene as a General Anesthetic in Man*

By MORRIS H. KAHN, M.A., M.D., F.A.C.P., and LLOYD K. RIGGS, Ph.D.,
New York City

THE effects of propylene, an unsaturated hydrocarbon of the olefine series, as an anesthetic in animals have been reported in a number of communications by Halsey^{4,5,6} and his coworkers, by Riggs^{1,2,3} and Goulden³ and by others, with interesting and encouraging results. All have reported that propylene was an effective anesthetic in concentrations of 40 to 60 per cent by volume. None of these authors have reported either an immediate or delayed toxic action of this hydrocarbon. It appeared, therefore, that propylene might with safety be tried out in actual surgical practice.

A group of research workers in New Orleans under the leadership of Prof. Halsey of Tulane University were the first to undertake clinical trials of propylene. Two cases of appendectomy were reported, in one of which marked irregularity of the heart developed toward the end of the period of anesthesia which was maintained for a little over thirty minutes.

Gwathmey, of New York, reported the use of propylene as an anesthetic for short dental operations, and observed no unfavorable heart symptoms.

Caine⁸ and Reynolds^{9,10} undertook

electrocardiographic studies on the action of propylene and other anesthetic gases. They found that non-anesthetic concentrations of propylene (25 per cent) caused ectopic ventricular beats which promptly disappeared when the concentration of propylene was lowered. Higher concentrations of propylene caused more frequent ectopic ventricular beats and runs of ventricular tachycardia of longer or shorter duration.

Chapman studied the action of propylene and of ethylene upon isolated turtle and frog hearts and found that "propylene in narcotic dosage is somewhat less depressing to these cold-blooded hearts than is ethylene."

In view of the above evidence Riggs and Goulden pursued further their studies on the physiologic action of propylene, giving special attention to its action upon the heart, and studying carefully the mechanism of death, watching the time of the cessation of respiration and of the heart beat. They employed cats, dogs, guinea-pigs and rabbits. Their results tended strongly to confirm their previous observations that the primary toxic action of propylene is upon the respiratory center, and quite secondarily upon the heart.

*Submitted for publication, April 15, 1931.

METHOD OF ELECTROCARDIOGRAPHIC STUDY

In view of these studies it appeared desirable to proceed with electrocardiographic studies on the human subject under propylene anesthesia. Dr. Lloyd K. Riggs offered himself as the subject of these experiments which were carried out at the Beth Israel Hospital in New York City. Dr. Riggs submitted himself to general anesthesia two or three times each day that the experiments were conducted, at intervals sufficient to permit the dissipation of any possible overhanging effects from one period of anesthesia to the next. The experiments were conducted at weekly intervals, and the anesthetic was administered two or more hours after a light meal but with no other preparation.

A length of rubber tubing held in the patient's hand was connected to a tambour and indicator which swung in front of the slit of the camera of the electrocardiograph. This was used to indicate each inspiration of the patient until he became unconscious, and again his respirations when he remembered to signal as he recovered from the anesthetic.

At first continuous records were taken in either Lead I, 2 or 3 as indicated in the tables. Subsequently it was considered equally adequate, during more prolonged anesthesia, to take short strips of record at definite intervals of one-quarter to one minute. Very careful analyses were made of the electrocardiographic films under the following headings:

1 The intervals between respirations, from the first exhibition of the

anesthetic until anesthesia was complete.

2 Adding these, we ascertain the length of time it required for propylene to anesthetize the patient.

3 The R-R interval in seconds indicates the rate of the heart beat in very exact figures.

4 The P-R interval indicates the conduction period in the heart and suggests the central nervous effects of propylene upon the heart mechanism.

5 Other miscellaneous effects, if and as they are encountered.

METHOD OF ANESTHESIA

Propylene had been freshly prepared the day previous to the experiments in various concentrations and was administered under atmospheric pressure by displacement with water. At first it was used in a freshly prepared mixture consisting of propylene 40 per cent, oxygen 20 per cent and the rest nitrogen. This applies to Experiments 1 and 2. In Experiments 3, 4 and 5 we used propylene 50 per cent, oxygen 20 per cent and nitrogen 30 per cent. In experiment 6 we used 75 per cent propylene and 25 per cent oxygen. In Experiments 7, 8, and 9 we used 50 per cent propylene, 20 per cent oxygen and 30 per cent nitrogen.

In every case the anesthesia was maintained for a period of a few minutes, and in the last experiment it lasted 16 minutes.

GENERAL EFFECTS OF THE ANESTHETIC

During administration of propylene, in all but the last experiment, the respirations continued entirely regular as is indicated in the tables by the time

intervals between respirations After the first few breaths, there was usually slight reddening of the eyelids with some lacrimation and flushing of the face This was more marked with a high concentration of the anesthetic Apparently the irritation was more than conjunctival as sometimes coughing would occur from pharyngeal irritation Just before the patient became unconscious there was noted contraction of the left leg and sometimes

also flexion of the right leg which quickly subsided and the legs would remain entirely limp Otherwise the progress of the anesthesia was uneventful and gradual, and after an average period of ten breaths anesthesia was complete During this time pinching or sticking the patient with a pin indicated complete insensitiveness The tables 1 to 9, show the rapidity with which the anesthesia produced unconsciousness

The heart beat remained unchanged				
Recovering from the Anesthetic		80	75	14 "
Remarks	Lead 2 used Propylene 50%, Oxygen 20%, Nitrogen 30% Depression of the respiratory center occurred with cessation of breathing for about one minute, while the heart beat was not appreciably affected			

During anesthesia in all but the last experiment the patient's breathing continued regular. There was no further lacrimation nor any movement of skeletal muscles until the commencement of recovery from the anesthetic. With that, the patient gradually opened his eyes, looked about him, smiled, swallowed, drew his right hand up to his mouth with a motion as if to wipe his lips, and felt for the tubing of the signal to press, that being apparently the prompt recollection. The return of the signal on the film was a suitable indication of returning consciousness. There was no feeling of nausea or vomiting during any of the experiments, and no feeling of any illness at all. After a maximum of two minutes from the removal of the anesthetic, consciousness was complete. The patient desired to sit up and inquired how the anesthesia had progressed.

ELECTROCARDIOGRAPHIC EFFECTS OF PROPYLENE

A preliminary electrocardiographic study was made before each experiment to ascertain the normal status of the individual. The electrocardiogram of Dr. Riggs was entirely normal, with moderate voltage, showing all the waves upright in the three leads, of normal duration and normal time relations, and fairly well marked sinus arrhythmia.

During the progress of the anesthesia the sinus arrhythmia became less distinct. We consider this, as shown by the graph (figure 1), a quite definite effect of propylene. In no experiment was there evidence of any sudden change of rate, except that resulting from the lessened sinus arrhythmia. In each of the experiments, when the patient aroused from the anesthesia, the pulse rate was two to ten beats lower.

FIG 1
Graph showing the effect of propylene anesthesia on sinus arrhythmia
(From experiment I)

than at the beginning of the anesthesia. The rate and the sinus rhythm returned to their original status within a few minutes after recovery from anesthesia. The character of the waves and the voltage remained unchanged during the experiments. No aberrant conduction tract was noted in any films, and no premature beats or any other form of irregularity occurred.

SUMMARY AND CONCLUSIONS

Electrocardiographic studies were made on the human subject of the effects of propylene as a general anesthetic. From their previous experimental work with animals Riggs and Goulden had come to the conclusion that the primary toxic action of propylene is upon the respiratory center, and quite secondarily upon the heart. The present study corroborates this conclusion for the human subject as well.

Propylene used as a general anesthetic in man produces complete anesthesia after an average of eight inhalations. There occurs no struggling or any reactive symptoms during the period of induction. During complete anesthesia the breathing is quiet and regular. The heart remained uninfluenced by the anesthetic except for a diminution of sinus arrhythmia during complete narcosis. The pulse rate and the character of the pulse as well as the electrocardiogram remained unchanged. Recovery from the anesthetic was prompt in each instance, with remarkably immediate return of memory, the patient promptly pressing his hand signal, believing that he was "still going under" after even ten minutes of complete anesthesia.

The quicker induction resulted when the mixture contained 50 per cent of propylene.

Editorials

HEREDITY OF ELLIPTICAL ERYTHROCYTES (OVALOCYTOSIS)

An interesting sequel has appeared to a study which was published in the *ANNALS* in 1929 of a family showing elliptical erythrocytes. In this paper by Hunter and Adams¹ personal observations were reported of three generations of a family of Dutch extraction, one member of which was living in Portland, Oregon, and the others near Missoula, Mont. Twelve members of this family were found to exhibit the anomaly in question, consisting of the presence in the circulating blood of elliptical, elongated and irregularly shaped erythrocytes. Differences were recognized and established between this condition and the more common sickle cell anemia. Several members of the family were more or less anemic and one showed a marked anemia, which improved under liver therapy. The twelve individuals showing the anomaly were members of three generations: a grandfather, each of his eight children, five boys and three girls, and three of six grandchildren, a boy and two girls, who were children of two daughters in the second generation. Prior to the emigration of the grandparents to this country none of the family, as far as known, had ever been outside the boundaries of Holland. For generations, the men were farmers and lived in the village of Zevenhuisen near

Amsterdam. This paper attracted the attention of Professor A. A. Hymans van den Bergh of the University of Utrecht, not only because it added a considerable number of new cases of this anomaly in which he was already interested, but also because the family was of Dutch extraction. He accordingly obtained the family name from the American authors and through a member of his staff investigated the branches of the family still resident in Holland. The results of this search have now been published.² Although the investigation was rendered difficult and in part incomplete because of the dispersion of the family and the refusal of certain of the parents to permit examination of their children, four additional examples of the anomaly were discovered. It was learned that the branch of the family in America had originated from the third marriage of the great grandfather, who had been married four times. From the first marriage there was no issue. Among the descendants in the lines resulting from the second and fourth marriages there was not a single example of elliptical erythrocytes.

¹HUNTER, WARREN C. and ADAMS, RICHARD B. Hematologic study of three generations of a white family showing elliptical erythrocytes, *Ann Int Med*, 1929, 11: 1162-1174.

²VAN DEN BERGH, A. A. HYMANS. A propos des hématies elliptiques (l'ovalocytose), *Rev Belge d Sci Med* 1931, 33: 683-688.

It therefore was evident that the anomaly had been introduced by the third wife. Accordingly, the investigation was broadened to include her collateral lines. It was found that she was one of seven children, all deceased, but only certain of the children of one of her sisters could be examined. In this family of eight children, three of the five examined were found to have elliptical red blood cells. A daughter of one of these made the fourth example in this line, and the sixteenth in the combined group. It is unfortunate that the numerous other collateral lines could not be investigated. From the combined genealogical charts of Hunter and Adams and of van den Bergh, it is shown that in this family the condition of having elliptical erythrocytes is inherited as a dominant trait, appearing only in the offspring of affected individuals and is transmissible by either sex. This affords another striking example of the inheritance of a hematic condition.

SIGNIFICANCE OF POSITIVE ASCHHEIM-ZONDEK TEST IN THE MALE

The biological relationship between host cells and tumor cells in patients with malignant teratomas of the testis containing chorionic epithelial structures is unlike that which can occur in the male under any other circumstances. If the included blastomere theory of the origin of complex teratomas of this type is accepted, it means for the male that in his testis there is growing a structure composed in part of the fetal components of the placenta belonging to his included twin brother. The adult male body is thus subjected

to hormonal influences normally experienced only by the female. That significant hormonal activity attaches to this neoplasm has been known for a good many years. Enlargement of the breasts is an extremely common finding with testicular chorio-epithelioma (malignant syncytioma), so that the examining physician has utterly failed in his duty to his patient if he does not make a careful examination of the testes when confronted by gynecomastia. If no intrascrotal tumor is found, but one testis is undescended, the cryptorchid is under a special burden of suspicion. If histological examination of the breast is possible, it will be found that the gynecomastia is of the type of a functional hypertrophy rather than the excessive fattiness of the enlarged breasts of pituitary dystrophy. There is clinical evidence of a quantitative relationship between the amount of living chorio-epithelial neoplasm and the degree of hormonal activity. In an instance known to the writer a surgeon removed a male breast showing marked enlargement due to functional hypertrophy. At the suggestion of a pathologist he enlarged his field of physical examination and found a testicular neoplasm which, when removed, proved to be in part chorio-epitheliomatous. The remaining breast, which was enlarged, but to a less marked degree than the one removed, decreased to about normal size before the patient left the hospital. However, when he returned a number of months later with innumerable metastases, all of which showed the usual mélange of syncytial cells and those from the Langhans' layer, the remaining breast

had reached a size larger than that of the other at the time it was amputated. This constituted an unintentional, but none the less controlled, biological experiment.

Further evidence of the hormonal aspect of this neoplasm rests on the occasional observation that after the removal of a primary chorio-epithelioma, its secondaries may undergo spontaneous retrogression. Unfortunately, this is apparently a rare occurrence which is limited to the less malignant forms and has been described only for the similar tumor in the female following pregnancy, in which the genetic relationship between host cells and neoplasm cells is more remote.

It is not surprising, in view of these clinical evidences, that a biologic means of detecting this hormone should be found in the Aschheim-Zondek reaction for the recognition of the presence of Prolan A. A summary of the scant earlier data on this subject and considerable new evidence are found in an extremely interesting paper by Ferguson and his associates¹ at the Douglas Research Laboratories of the Memorial Hospital, New York City. The question is complicated by the occurrence of positive reactions in the presence of carcinoma in the female, especially of genital carcinoma. Thus Zondek found forty-five positive reactions among fifty-five cases of genital carcinoma in non-pregnant women, and five positive reactions in a

group of fourteen women with extra-genital carcinoma. At the time when Ferguson's paper was written Zondek had reported upon a group of men with extragenital carcinoma, thirty in all, of whom four gave positive reactions, and upon a group of four men with genital carcinoma, of whom two with carcinoma of the prostate gave negative reactions and two with neoplasms of the testis, not verified histologically, gave positive reactions. Heidrich and Fels had found a positive reaction in a man, thirty-five years old, with a proved chorio-epithelioma of the testis. Ferguson and his group found negative reactions in fifteen men with normal testes, including three who were normal and twelve with extratesticular carcinoma. Negative reactions were found also in twenty-four with non-malignant lesions of the testes, only one of which was a blastoma. Eight cases with testicular teratoma all gave positive reactions. Of four cases of teratoma without clinical evidence of disease for three months to three years, three had negative reactions and the fourth who had had the right testis removed ten years before under a diagnosis of sarcoma and the right testis removed three months before for a proved embryonal carcinoma, gave a positive reaction. The suggestion is made by the authors that a lack of balance of the hormone of the anterior hypophysis due to his castrate condition might explain the positive reaction of this eunuch, but certainly insufficient time had elapsed to eliminate the possibility of sub-clinical metastasis. From the results reported, it would seem that the Aschheim-Zondek reaction provides a re-

¹FERGUSON, RUSSELL S., DOWNES, HELEN R., ELLIS, EDWARD, and NICHOLSON, MARY E. Preliminary note on a new method of differentiating the testicular tumors by biological means, *Am Jr of Cancer*, 1931, **xv**, 835-843.

markably consistent method of determining the presence of malignant tumors of the testis at an early date (43 days from the known date of onset in one instance) in the course of the disease. The importance of this in differential diagnosis and in the presence of cryptorchidism can readily be appreciated. From the results available this reaction does not appear to differentiate chorio-epithelioma from other forms of malignant teratoma of the testis. It would require serial sections of the entire growth, however, to rule out beyond any doubt, the possibility that malignant syncytioma was present. It is probably that most, if not all, testicular teratomas are originally trigeriminal and that one or more cell types, acquiring the attributes of malignancy, outgrow all of the others.

A still broader significance may at-

tach to this line of investigation. Normal chorionic syncytium and cancer cells have much in common: extraordinary reproductive energy, rapidity of growth, invasive power coupled with destruction of the recipient tissue, and striking facility for hematogenous dissemination. When chorionic syncytial giant cells lodge in the lung, as they do with every childbirth, they soon die; but when carcinoma cell emboli lodge in the lung, they survive and grow only too frequently. One succumbs, apparently, to an anti-syncytial hormone; against the other no such defensive mechanism seems to be at hand. The Aschheim-Zondek reaction, or modifications of the same principle, may eventually give much information about the biologic relationship of the cancer cell to its host tissue, as it affects the hormonal balance of the entire organism.

Abstracts

The Diagnostic Program in Food Allergy
By WARREN T VAUGHAN, M D (Am
Jr Med Sci, 1931, clxxxii, 459-467)

From the past history, and the family history, the probability of the existence of an allergic state can usually be determined, and the history of each attack may, if carefully gone into, furnish good clues to foods which should be suspected. Thorough physical examination and careful laboratory investigation must be utilized in order to recognize such associated organic diseases as may be present. Both the scratch method and the intradermal technic have a distinct place. The latter is much the more sensitive but should not be done without preliminary scratch studies. If the skin tests are negative or if, after trial, it is learned that all of the allergenic foods have not been discovered, two other methods of study remain. If the symptoms manifest themselves at intervals of several days, the *food diary* in which the patient tabulates all substances which he ingests and notes the appearance of allergic manifestations may reveal the offending substances. If the symptoms are fairly constant or appear at frequent intervals, the *trial diet* may be of the greatest value. In this connection the author emphasizes the importance of giving due regard to the biological grouping of food substances. When one member of a botanical food group has been proven allergenic to an individual, other members of the same group may cause allergic symptoms, even though their skin test reactions have been negative. Sometimes a positively reacting member of a group is found to give rise to no symptoms whatsoever, while a negatively reacting member of the same group does cause trouble. However, if one is sensitive to one member of a group, it does not necessarily follow that all other members will produce symptoms. On the background of these various considerations, a basic list of foods for use in the formulation of the trial diet

is proposed. Any such diet must be followed rigorously for at least two weeks before one can be certain of the results.

I Anemia of Dogs Produced by Feeding of the Whole Onions and of Onion Fractions II Anemia in Dogs Produced by Feeding Disulphide Compounds By O M GRUHIT, M D, (Am Jr Med Sci, 1931, clxxxii, 812-815, 815-820)

The feeding of raw or autoclaved onions or their juice to adult dogs resulted in a severe anemia, confirming the findings of Sebrell in this respect. The animals were fed both the raw and the autoclaved onions in daily doses of 15 gm per kilogram of body weight, and the onion juice in equivalent amounts of 10 cc per kilogram. Uniform results were obtained from the three forms of feeding. Severe reduction in the number of red cells and in the hemoglobin occurred on the seventh or eighth day, when six feedings of onion had been given. There was a simultaneous increase in the white cell count. Hemolysis must play an important part in the red cell destruction for the blood serum became red with hemoglobin. In every case, following the maximum red cell destruction, the animal developed tolerance to onion in any of the three forms administered so that further feeding had no effect on the blood elements. The feeding of the steam distillate of fresh onions and of the residue from the distillation of onions caused little or no change in the blood of dogs, although the distillate possessed an extremely strong odor of onions, and dried onion juice was less effective than the juice itself. It was believed that the active agent in producing the observed effects was probably oil or onions of which allyl propyl disulphide is the chief constituent. Since this compound was not available, closely related substances containing the disulphide linkage were tried. It was found that n-propyl disulphide and di-p-tolyl disulphide caused

severe anemia in dogs through a hemolytic action upon the red cells. The rapid hemolysis was followed by a high degree of leukocytosis and marked signs of red cell regeneration. The benzyl disulphide, although isomeric with the di-p-tolyl disulphide, lacks entirely the hemolytic action of the latter. Repetition of a course of treatment with n-propyl disulphide showed no evidence of the acquisition of tolerance such as followed onion feeding.

Autopsy Observations on One Hundred and Sixteen Cases of Malignant Disease, in Eighty-Nine of Which Experimental Injections of Suprarenal Cortex (Coffey-Humber) Were Given By HOWARD A. BALL, M.D., (Am. Jr. of Cancer, 1931, xv, 1352-1360)

The 116 cases of malignant disease used in this study were divided into three groups, a *basic control series* composed of 25 cases of malignant disease, previously examined post-mortem by the author, in which application had been made for extract injection, but in which death had occurred before any extract was administered, a *relative control series* consisting of 47 cases receiving from 1 to 15 injections, or not more than 105 cc of the experimental adrenal cortex extract, and an *experimental observation series* consisting of 42 cases in which more than 15 injections, or more than 105 cc of the extract, had been given. Since necrosis and sloughing were the chief anatomical changes claimed by Coffey and Humber in their patent application, these manifestations were watched for especially. Necrosis and sloughing were observed frequently and occasionally seemed to be of greater degree or further extent than one would be led to expect from observation of similar uninjected cases. They occurred, however, without correlation to the total amount of extract injected and the difference in these respects among the three series was too slight to be significant. Likewise no essential difference in the incidence of necrobiosis was found on microscopical examination, using nuclear fragmentation and "replacement fibrosis" as criteria. In 28 per cent of the 80 cases which had received the extract, metastases were found in the adrenals. No essential change from the

usually observed characteristics of malignant tissue in far advanced cases could be determined in the two series that received the experimental suprarenal cortex extract (Coffey-Humber), and there were no significant differences between the series that had received less than 15 injections and that which had received more than that amount of treatment.

Extensive Atrophy of Subcutaneous Fat Following the Repeated Injections of Insulin By JOHN R. WILLIAMS, M.D., F.A.C.P. (Jr. Lab. and Clin. Med., 1931, xvi, 1911-1197)

That it is important for the patient self-administering insulin to vary the site of the injection, and equally important for the physician to make occasional physical inspections of the regions used, is shown by the increasing group of cases in which local atrophy of the subcutaneous fat occurs. The author reports and illustrates such a case. A woman, aged forty-four years, who had been taking two doses of insulin daily for nearly three years remarked upon the hollows in her thighs. Examination revealed a marked atrophy of the subcutaneous fat on the anterior surfaces of both thighs. The atrophic areas were irregular in shape and from 8 to 15 cms in diameter with the longer axis parallel to that of the thigh. These cavities were from 2 to 3 cms deep and gave the impression that the fat had been completely excavated from beneath the skin of the involved areas, for the muscles and blood vessels beneath could be distinctly felt. There was no evidence of soreness or inflammation. Similar changes were noticed in a girl who was taking four small doses of insulin daily. In this case, after avoiding injection of the areas of atrophy for some time the defects disappeared, apparently being filled in by new fat. The cause of this unusual atrophy is unknown, but a low grade inflammation with fibrosis may be the important factor.

Provisional Birth, Death, and Infant Mortality Figures, Birth Registration Area, 1930 (Public Health Reports, 1931, xlv, 2373-2376)

The Department of Commerce, through the Bureau of the Census, Division of Vital

Statistics, announces that in 1930 in the birth registration area (exclusive of Utah) there were reported 2,190,047 live births. This is an increase of 15 per cent over the number reported from the same area in 1929. Birth rates were higher in 26 states in 1930 than in 1929. In both years New Mexico has had the highest birth rate of any state, while Oregon has had the lowest rate in each of the two years under comparison. In the birth registration area (exclusive of Utah) the death rate in 1930 was 11.3. This is 0.6 lower than for 1929. The infant mortality rate for 1930 was 64.2, the lowest since the establishment of the birth registration area in 1915. In thirty-seven states an infant mortality rate was attained lower than that of the preceding year.

Carcinoma of the Stomach in a Negro of Twenty-Four Years By JAIME DE LA GUARDIA. United Fruit Company, Medical Department, Nineteenth Annual Report, 1930, 144-148.

The occurrence of an advanced scirrhus carcinoma of the stomach in a Haitian negro 24 years of age is of interest from the standpoints both of age incidence and race incidence. The history revealed the onset of the condition to have antedated his entrance into the hospital and subsequent diagnosis by at least two years. A wide resection of the stomach was done with gratifying immediate post-operative results. The patient died about four months later of recurrence and generalized carcinomatosis.

Reviews

The Renal Lesion in Bright's Disease By THOMAS ADDIS, Professor of Medicine, Stanford University, and JEAN OLIVER, Professor of Pathology, Long Island College of Medicine, Formerly Professor of Pathology, Stanford University. xi + 628 pages, 170 full page plates, 2 in color, 21 text illustrations and 1 folding table. Paul B. Hoeber, Inc., New York City, 1931.

One need not go far into this book by Addis and Oliver to realize that he has before him a work which is unusual in its straightforward objectivity. It is easy to prophesy for it an influence which may pervade medicine for a long time to come. It does more than set forth that which its title foreshadows, it points the way to a method. As did Bright in 1827 and Volhard and Fahr in 1914, the authors develop a comparison of clinical and pathological facts in order to determine the degree of correlation between them. Hence the method must be objective and it must be characterized by strict intellectual honesty. That such is the case there is abundant evidence throughout the work. Clinical methods and definitions in connection with the renal lesions of Bright's disease are first

set forth, with a consideration of normality in the characteristics of the urine. More than one practitioner will be surprised to learn that the average rate of cast excretion in 74 supposedly normal medical students was 1040 per twelve hours. The pathological methods of qualitative and quantitative investigation of the renal lesions are also presented with carefully considered definitions of the terms used. The detailed clinical and pathological observations of the 72 cases used in the investigation occupy the next 350 pages. Each case is illustrated by two photomicrographs, one a low power view for general topography, the other of sufficiently high magnification to show the simpler cellular detail and especially valuable because of the wide area utilized, averaging four glomeruli to the field. The clinical and pathological observations are then correlated and a theoretical description of the course and sequence of the pathological processes developed. From this analysis a classification of Bright's disease satisfactory to both clinician and pathologist is proposed. The authors recognize as the main group—hemorrhagic Bright's disease with initial latent, active and terminal stages, diac-

erative Bright's disease, and *arteriosclerotic* Bright's disease. In both content and format this book is highly to be commended. One cannot but admire the courage of the publisher who dares to illustrate so profusely, for the illustrations of this book constitute an atlas of the pathology of nephritis. To both clinician and pathologist this work will be of very great value.

Gould's Medical Dictionary. By GEORGE M. GOULD, A.M., M.D., Edited by R. J. E. SCOTT, M.A., B.C.L., M.D. Third edition, revised and enlarged, with illustrations and 173 tables. 1538 pages. P. Blakiston's Son and Company, Philadelphia, 1931. Price, in rigid fabrikoid with thumb index, \$7.50, in flexible binding, plain, \$7.00, with thumb index, \$7.50.

This new edition of Gould's Medical Dictionary requires no introduction, for more than 800,000 copies of its predecessors in their various forms have been sold. When the "Pocket Medical Dictionary" came out in 1892 it contained 12,000 defined words. The edition immediately preceding the one now under review contained over 83,000 words and to that compilation many new terms have been added in the present revision. Certain omissions in the preceding edition, to which attention was called in a review in the *ANNALS* at that time, have been remedied, although it is not clear why 'blastophthoria', thus introduced, is capitalized. Preference is now given to the retention of the final *e* in that series of chemical terms from which it was dropped a number of years ago on the recommendation of the American Association for the Advancement of Science. This is in accord with present day orthography. The inclusion of an enormous store of useful information in tabular form has been an important feature in this series. Among the 173 tables in this edition there are a number of new tables of bacteria, metazoa and pathogenic protozoa, also the International Table of the Causes of Death. In the table of micro-organisms the original names are conveniently arranged in parallel columns with those of the new classification. These

tables are made useful to the great majority of physicians whose bacteriology was not that of the last few years by basing the alphabetical arrangement on the old names which are so much more familiar. Numerous illustrations add greatly to the value of descriptive definitions and those which differentiate between closely similar structures. A medical dictionary should be the most used text of both medical student and practitioner, and this new Gould will be found eminently satisfactory in every particular.

Recent Advances in Radiology. By PETER KERLEY, M.B., B.Ch. (N.U.I.), D.M.R.E. (Camb.), Assistant Radiologist, Westminster Hospital, Radiologist, The Royal Hospital for Diseases of the Chest viii + 324 pages, 120 illustrations. P. Blakiston's Son and Company, Philadelphia, 1931. Price, \$3.50, net.

The significant advances in the physical aspect of radiology, both technical and structural, are largely omitted from this book, for its purpose is to set before the general practitioner, the internist, and the surgeon, that which each must know about the present state of the subject in its clinical applications. Each must know the constantly expanding field of applicability of radiological methods of investigation, their limitations and the underlying principles in the interpretation of radiographs. This means that throughout the book the method of approach is that of correlation of the pathological changes with the radiological appearances. The present state of x-ray therapy is presented in a much compressed final chapter. Not all will agree that "the radiation treatment of malignant disease has now passed through the troublesome optimistic and pessimistic periods, and is established on a scientific basis." However, this chapter is largely free from unjustified enthusiasm for methods of treatment for specific neoplastic conditions and presents those conflicting views which show that the question is still unsettled. One of the most valuable of the many excellent features of the book is the emphasis placed upon what constitutes a suitable film for a particular purpose. Under lung, for instance, are sum-

marized the results of investigations carried on in the Royal Chest Hospital during the last five years. It was found that early tuberculosis is best seen in a film which shows the subclavian arteries, the inferior vena cava, and the normal interlobar pleura between the right upper and middle lobes. The demonstration of these three shadows or, at least, of the vascular ones, was then decided upon as an essential criterion of a suitable film. This text is a worthy addition to the Recent Advances series.

Textbook of Histology for Medical and Dental Students. By EUGENE C. PIETTE, M.D., Pathologist and Director of the Laboratory of the West Suburban Hospital, Oak Park, Illinois, Consulting Pathologist of the Chicago State Hospital, Chicago, Illinois, etc. xvi + 466 pages, 277 illustrations. F. A. Davis Company, Philadelphia, 1931. Price, \$4.50, net.

We are told in the preface of this textbook of histology, intended primarily for medical and dental students, that an author must be first of all a censor, suppressing and omitting anything incomplete and doubtful. There are a number of assertions admitted here, however, which might well have been subjected to a more rigorous censorship. For instance, the statement is made that the hearts of human cadavers have been revived *several days after death* by injecting warm Ringer's solution with glucose into the coronary arteries, such hearts resuming contractions and continuing vital specific activity. Technical methods are briefly surveyed in fifteen pages in which paraffin sections are described as being cut with the knife perpendicular to the long dimension of the piece of tissue, apparently serial sections alone being considered. The celloidin sheet methods for handling paraffin sections are not mentioned. Crenated erythrocytes are said to be of the shape of thorn apples, missing the point that the thorns of the thorn apple (by which hawthorn rather than *Datura stramonium* is usually understood in this country) are not on the fruit. Various other assertions cannot be passed by without a challenge. There is far from general acceptance of the statement that there

are no hemolymph nodes in man, and what reason is there for considering the intrafusal fibers of the muscle spindle as *immature* muscle fibers? Many subjects receive inadequate treatment to meet the needs of the medical students. The palatine tonsil is disposed of in six lines, while the teeth, in probable anticipation of use of the book in schools of dentistry, are granted thirty pages. This book is very well printed and the illustrations, of which none are original, are well reproduced. In view of the effort which has gone into its production, it is a matter for regret that the text does not meet more fully the needs of the student and of the hospital pathologist.

Streptococcic Blood Stream Infections. By GEORGE E. ROCKWELL, M.A., M.D., Associate Professor of Bacteriology, College of Medicine, University of Cincinnati, Member of Senior Medical Staff, Bethesda Hospital, Assistant Director of Bacteriological Service, General Hospital of Cincinnati. ix + 73 pages. The MacMillan Company, New York City. 1931. Price \$1.75.

This short monograph discusses streptococcic blood stream infections under eight chapter headings: Infection, Resistance, the Streptococci, the Patient, the Diagnosis, the Blood Culture and the Treatment. The presentation of this material is far from exhaustive, the content not exceeding that which might be reasonably required of a medical student. There are frequent misspellings of such ordinary terms as 'aldehyde', 'tonsillitis', and 'cholecystitis', and marked inconsistency in orthographic style. Words of the series having the root 'αιμα' at the beginning, such as *hemolysis* are spelled with the diphthong, while the single vowel is used in all forms having the same root at the end of the word, such as *septicemia*. The omission of *endocarditis verrucosa* and *scarlatina* from the index reveals the level of content. The chapter on treatment is the best part of the book. Here the author writes vigorously and convincingly in evaluating the various therapeutic measures which have been proposed.

College News Notes

PROPOSAL OF NEW MEMBERS

The attention of all Masters and Fellows of the College is called to the By-Laws, Article V, Section 3 (c), Paragraph 2

"After 1931, a candidate for Fellowship shall be eligible only if already an Associate, except upon recommendation of the Committee on Credentials, by reason of very special qualifications"

Masters and Fellows who have candidates to propose for Fellowship should see that the forms are executed and filed in the office of the Executive Secretary of the College before December 31, 1931

Attention is also called to the "Introductory Statement" appearing in the 1931-32 Directory of the College, especially paragraph 1 on page 22. Those Associates who have been elected since April 1, 1929, according to the By-Laws, must qualify for Fellowship within a period of from three to five years from the time of their election. Article VI, Section 3, of the By-Laws, provides that at the expiration of three years, an Associate shall be notified in writing of his eligibility for advancement to Fellowship during the next two years, providing he shall meet within that time the requirements necessary for Fellowship. If not elected to Fellowship within five years, his Associateship will automatically cease. In accordance with the above provisions, Associates eligible for proposal to Fellowship at the next Clinical Session have been notified.

Proposals for Fellowship now on file will be acted upon at a late autumn meeting of the Board of Regents. Proposals for Associateship will be acted upon during the San Francisco Clinical Session, due to the fact that they must first be approved by the Board of Governors before election by the Board of Regents. All proposals must be filed thirty days in advance of action.

1931-32 DIRECTORY

The Executive Secretary of the College completed the publication of a new directory of the Masters, Fellows and Associates during the past summer, and distributed a copy to all members in good standing on September 20. Although the contents have been limited to the most important biographical data, the volume has grown to one of four hundred and thirty-three pages, the compilation of which was a considerable task. Some members failed to return the biographical data sheets, in which cases their previous data were published. However, the great majority co-operated promptly, and a directory to a high degree inclusive and up to date has been produced. Members are requested to advise the Executive Secretary of any misprints, incomplete or imperfect data, so that corrections may be made in the next issue. This directory has become an important reference and guide for physicians and institutions all over the country.

Any member of the College in good standing who by any chance failed to receive the above mentioned directory during September is requested to communicate with the Executive Offices of the College. It has been determined that some copies were held at the Canadian Customs Office and not delivered. In a few other instances, copies may have failed to reach their destinations due to changes of address.

Dr. George E. Pfahler (Fellow), Professor of Radiology, Graduate School of Medicine of the University of Pennsylvania, attended the Third International Congress of Radiology held at the Sorbonne in Paris during the past summer. Dr. Pfahler presented a paper entitled "Roentgen Therapy in Carcinoma of the Breast—A Statistical Study of the Results in Over 1,000 Cases".

At the opening of the Congress, Dr. Pfahler presented an ivory gavel carved from the

tusk of a mastodon, imbedded for probably a million years in the ice of Alaska, to the President of the Congress, Dr Antoine Béclere. In his presentation, Dr Pfahler explained that not all in America is new and young, but that we too have our antiquities

Dr Edward A. Strecker (Fellow), Philadelphia, has been appointed Professor of Psychiatry in the University of Pennsylvania School of Medicine

Among recent appointments in the Graduate School of Medicine of the University of Pennsylvania are the following

Dr Ralph Pemberton (Fellow), Professor of Medicine,

Dr William D. Stroud (Fellow), Professor of Cardiology,

Dr Truman G. Schnabel (Fellow), Assistant Professor of Medicine

Dr Carl V. Vischer (Fellow), Philadelphia, is the author of an article entitled "Student Instruction in the Medical Outpatient Department of Hahnemann Hospital of Philadelphia", which appeared in the September number of the Hahnemannian Monthly

Dr G. Harlan Wells (Fellow), Philadelphia, is the author of an article entitled "Care of the Heart in the Pneumonia Patient", which was published in the September number of the Hahnemannian Monthly

Dr Ralph Bernstein (Fellow), Philadelphia, discussed the Dermatologic Toxemias of Pregnancy in a contributed article which appeared in a recent issue of the Hahnemannian Monthly

Dr William B. Porter (Fellow), Professor of Medicine at the Medical College of Virginia, and Dr Albert H. Hoge (Fellow), President-Elect of the West Virginia State Medical Association, were speakers at an alumni meeting of the Medical College of Virginia held at Charleston, October 12. Dr Walter E. Vest (Fellow), Huntington, was Chairman of the Committee

Dr Porter and Dr Hoge both addressed the Kanawha County Medical Society at Charleston, October 12

Dr Hoge addressed the West Virginia State Hospital Association at Huntington, September 21, and was also Toastmaster at their annual banquet

Dr Vest was elected President of the West Virginia State Hospital Association, September 21

Dr Henry M. Moses (Fellow), Brooklyn, N. Y., has been appointed Professor of Clinical Medicine at the Long Island College of Medicine

On October 7, Dr Moses presented a paper on "The Clinical Findings and Methods Used in the Diagnosis of Pulmonary Neoplasms" in a symposium on this subject at the staff meeting of the South Nassau Communities Hospital, Rockville Centre, New York

Dr John V. Barrow (Fellow), Los Angeles, lectured before the Hollywood Academy of Medicine, September 24, his subject being "Pathology and Treatment of Amebiasis, with Motion Picture Demonstrations of Organisms and Lesions"

D. R. Manning Clarke (Fellow), Los Angeles, has been elected Secretary of the Medical Section, California State Medical Association, for the year 1931-32. The next annual session will be held in Pasadena

D. Samuel Ayers, Jr. (Fellow), Los Angeles, is co-author with Nelson P. Anderson and Esther M. Youngblood of an article entitled "Fumigation as an Aid in the Control of Superficial Fungus Infections" in the Archives of Dermatology and Syphilology, August, 1931

Dr Ayres is also co-author with Dr Anderson of an article entitled "Dermatitis Medicamentosa Due to Ephedrine" appearing in the August 15, 1931, issue of the Journal of the American Medical Association

Dr G. R. Maxwell (Fellow), Martinsburg, W. Va., has been elected Chair-

Staff of the Monongalia County Hospital Morgantown, for the year 1931-32

Doctors Simon R Blatteis, Frank B Cross, Henry M Moses and Philip I Nash (Fellows) have been appointed Professors of Clinical Medicine, and Doctors Murray B Gordon and Paul L Parrish (Fellows) have been appointed Professors of Clinical Pediatrics, at the Long Island College of Medicine. These appointments carry with them seats in the administrative faculty

Doctors E G Thompson, W C Colbert C H Sanford and A F Cooper (Fellows) have recently been advanced to Associate Professors of Medicine at the University of Tennessee College of Medicine Memphis

Dr B M Allen (Fellow), Wilmington Del, addressed the 142nd annual session of the Medical Society of Delaware, October 14, on "X-Ray Diagnosis of the Chest with Special Reference to Fluid"

Dr H O Colomb (Associate), formerly of Providence, R I, has been appointed Clinical Director at the Central State Hospital, Pineville, La., as of October 1, 1931

Dr Solomon L Cherry (Fellow), Clarksburg, W Va, discussed a paper on "Dental Foci of Infection and their Systemic Effects" at a joint meeting of the Harrison County Medical and Dental Societies on October 1

Dr E J Engberg (Fellow), St Paul, Minn, is the author of an article in Minnesota Medicine for October entitled, "Polymyositis in Minnesota"

Secretary Ray Lyman Wilbur who is President of Better Homes in America, has recently appointed Dr James M Anders (Master) Chairman of the Better Homes Committee of Philadelphia for 1932. Dr Anders has also been reappointed a member of the Board of Health of Philadelphia by the present Director of Public Health, Dr Orlando H Petty (Fellow)

At a Clinical Conference held under the auspices of the Staffs of the Leo N Levi Memorial Hospital and Charles Steinberg Clinic, both of Hot Springs National Park, Ark, October 1, 1931, the following Fellows of the College took part

Dr A G Sullivan—"Etiological, Anatomical and Physiological Factors in Heart Disease",

Dr D C Lee—"Laboratory Diagnosis of Syphilis with Demonstration",

Dr Grayson E Tarkington—"Dehydration in Epilepsy",

Dr G B Fletcher—"Types of Paralysis Points in Differential Diagnosis"

Dr Mitchell Bernstein (Fellow), Philadelphia, was elected a member of the Board of Trustees of the Philadelphia College of Pharmacy and Science at its semi-annual meeting, September 28, 1931

Dr J A Myers (Fellow), Minneapolis, has been promoted from Associate Professor to Professor of Preventive Medicine at the University of Minnesota

On September 22, Dr Myers presented a paper before the annual joint meeting of the Medical Society of the County of Queens and the Queensboro Tuberculosis Association, on September 24, a paper before the general session of the 111th annual meeting of the Michigan State Medical Association, on October 2, a paper before the St Joseph, Missouri, Medical Society and the Missouri State Tuberculosis Association, on October 15, a paper before the Illinois State Nurses Association in Chicago, and on November 2, a paper before the Wisconsin Anti-Tuberculosis Association in Milwaukee

Dr William Devitt (Fellow), Founder and Directing Head of Devitt's Camp, Allenwood Pa, on September 18, 1931, was honored by the local Rotary Club of Milton at a dinner and reception given as a "means of expressing to the widely known physician the measure of esteem and devotion held for him by his associates in the club, as well as by the thousands of residents of the Susquehanna Valley who have witnessed

his successful efforts at the Sanitarium that bears his name"

Dr Robert G Torrey (Fellow), has been appointed Professor of Principles and Practice of Medicine, succeeding the late Dr L. Napoleon Boston, at the Woman's Medical College of Philadelphia

Dr J M Hutcheson (Fellow), Richmond, Va, and Dr D P Scott (Fellow), Lynchburg, Va, addressed the Mecklenburg County Medical Society, September 15, on "Clinical Aspects of Coronary Thrombosis" and "Treatment of Nervous Patients", respectively

At the Roanoke Meeting of the Medical Society of Virginia, October 6-8, 1931, Dr D C Wilson (Fellow), Professor of Nervous Diseases at the University of Virginia, and Dr Beverley R Tucker (Fellow), Professor of Neurology and Psychiatry at the Medical College of Virginia, were speakers in connection with the mental hygiene symposium

Dr Horton Casparis (Fellow), Professor of Pediatrics at Vanderbilt University, Nashville, as guest speaker before the Virginia Pediatric Society, October 7, used as his title "Tuberculosis in Children Prevention and Control"

Dr A L Gray (Fellow), Richmond, Va, is President of the Virginia Roentgen Ray Club, which held its annual meeting at Roanoke in connection with the state meeting, October 7

Dr John E Gardner (Fellow), Roanoke, Va, spent six weeks during the summer in special electrocardiographic work at the Johns Hopkins Hospital, Baltimore

Dr Beverley R Tucker (Fellow), Richmond, attended the International Congress on Nervous Diseases in Berne, Switzerland, during the past summer

Dr D T McCall (Fellow), Mobile, Ala, recently addressed the Monroe County (Ala) Medical Society

Dr Walter S Leathers (Fellow), Nashville, recently addressed a conference of public health workers of Kentucky, Tennessee and Missouri

Dr Lea A Riely and Dr John E Heatley (Fellows), both of Oklahoma City, Okla, gave addresses at the Osage County Medical Society's meeting on September 28, 1931—their subjects being, "The Clinical Aspects of Gall Bladder Disease" and "X-Ray Diagnosis of Gall Bladder Diseases", respectively

Dr Lewis J Moorman (Fellow), Oklahoma City, Okla, has been elected Dean of the University of Oklahoma School of Medicine

Dr John M Thorne (Fellow), Pittsburgh, addressed the McKeesport (Pa) Academy of Medicine, October 26th, on "The Management of Cardio-Renal-Vascular Diseases"

On the recommendation of the Committee on Reorganization of the Sea View Hospital, Staten Island, New York, June 30, 1931, Doctor Louis Faugeres Bishop (Fellow), has been reappointed Consulting Cardiologist at Sea View Hospital

Dr Samuel E Thompson (Fellow), Kerrville, Texas, has been re-elected President of the Southwest Texas District Medical Society

Dr Joseph McFarland (Fellow), Philadelphia, addressed the annual meeting of the Medical Society of Delaware at Wilmington on "Malignant Diseases of the Breast"

Dr Francis E Sencar (Fellow), Chicago, presented a paper on "Modern Conceptions Concerning the Treatment of Syphilis" before the Peoria City Medical Society, October 6

Dr Carl F Moll (Fellow), Flint Mich, was installed as President of the Michigan State Medical Society at Pontiac, September 24

Dr W Bernard Yegge (Fellow) of Denver addressed the Boulder County (Col) Medical Society, October 8, on "Diagnosis and Treatment of Gastric Ulcer".

Dr Henry F Smyth (Fellow), Philadelphia, discussed "The Toxicity of Methyl Alcohol" before the annual meeting of the American Public Health Association at Montreal, September 7-10, 1931

Dr Carl R Howson (Fellow), Los Angeles, addressed the Fresno County Medical Society, September 1, on the subject "Some Points in the Present-Day Treatment of Tuberculosis", and also the San Bernardino

County Medical Society, October 6, on "The Future of Medicine"

Acknowledgment is made of the following gifts of reprints by members to the College Library

Dr George B Fletcher (Fellow), Hot Springs Nat'l Park, Ark—I reprint,

Dr Gustave P Grabfield (Fellow), Boston, Mass—6 reprints,

Dr Samuel J McClendon (Associate), San Diego, Calif—4 reprints,

Dr Aaron E Parsonnet (Fellow), Newark, N J—2 reprints,

Dr Meldrum K Wylder (Fellow), Albuquerque, N M—I reprint

OBITUARY

DR ROBERT GIBBS DOUGLAS

Dr Robert Gibbs Douglas, Associate, Louisiana, died of malignant hypertension on July 23, 1931, aged 45 years

Dr Douglas was born in De Soto Parish, Louisiana, in 1885. He received his academic education at the University of Louisiana, while his medical degree was obtained from Tulane University of Louisiana School of Medicine in 1919. During 1920 his internship was spent in the City Hospital, St Louis, Missouri. He returned home for a year and associated in practice with Dr L T Baker of Dixie, Louisiana, where he remained until he became associated with the Highland Clinic in 1922. From that time until his death, Dr Douglas confined his work to the study and practice of internal medicine. He en-

deared himself to his associates and to the community in general. At the time of his death he enjoyed a very large practice.

Dr Douglas was a member and ex-President of the Caddo Parish Medical Society and a member of the Southern Medical Association, the Louisiana State Medical Association and the American Medical Association. He was elected to Associateship in the American College of Physicians during 1925.

He was a man of unusual ability, a gifted orator and a most lovable character, generous almost to a fault, never sparing himself in his endeavor to alleviate suffering. The Highland Staff has lost one of its most valuable coworkers and the community one of its most respected citizens.

Observations On Pneumococcus Type III Pneumonia*†

By FRANCIS G. BLAKE, A B, M D, F A C P, *New Haven, Conn*

DURING the last two decades there has been a gradually but steadily increasing tendency to classify pneumonia on an etiological basis rather than on the older, anatomical basis of Laennec, or at least, if the anatomical terms of lobar and bronchopneumonia are retained, to qualify them by an additional etiological diagnosis. This change which has taken place in the classification of pneumonia has undoubtedly occurred because of the increasing recognition of the fact that pneumonia comprises in reality a considerable group of quite different and distinct infectious diseases hitherto all classified under one or the other of two headings—lobar or bronchopneumonia, primarily on the basis of anatomical considerations, but also in part on symptomatology. Etiological differentiation has been particularly emphasized by Cecil¹, and has been ably discussed by Cole² in his DeLamar Lecture of 1927. In one of his concluding paragraphs Cole says, "acute lobar pneumonia due to pneu-

mococcus type I and acute lobar pneumonia due to pneumococcus type II are specific infectious diseases, just as typhoid fever is a specific infectious disease. The other varieties of acute lobar pneumonia are not such well characterized conditions."

Of these other varieties, pneumococcus type III pneumonia has seemed of particular interest for three reasons: first, because it has a very high case fatality rate of 40 to 50 per cent, secondly, because, although highly fatal, it is caused by a type of pneumococcus which apparently leads a harmless, saprophytic existence in the mouths of a considerable proportion of normal, healthy individuals³; and thirdly, because, in spite of this fairly wide distribution of type III pneumococci and consequent frequent opportunity for infection, the incidence of type III pneumonia is usually recorded as being relatively low when compared with that of pneumonia due to type I and to type II pneumococci, organisms which are not found in the mouths of normal individuals except in rare instances³.

Previous studies by Cecil, Baldwin and Larsen⁴ have suggested that these peculiarities of type III pneumonia may be related to its apparently preponderant incidence in the later decades.

*From the Department of Internal Medicine, Yale University School of Medicine and the Medical Service of the New Haven Hospital.

†Read at the Baltimore Meeting of the American College of Physicians, March 25, 1931.

of life, frequently in individuals who are the subject of chronic disease, and that in reality the type III pneumococcus is not the highly virulent organism for man which the high mortality of type III pneumonia would seem to indicate

In an effort to see whether additional information bearing on the foregoing suggestions might be obtained and also to characterize type III pneumonia more definitely as a specific disease, a detailed study has been made of 122 consecutive cases admitted to

group IV cases have not been analyzed, since they have not been classified into the numerous specific types of varied virulence and prevalence included in the group IV pneumococci.

INCIDENCE

The relative incidence of the type III infections is shown in table I and is comparable to that previously reported by others. Of the 606 cases of pneumococcal pneumonia in the series, 122, or 20 per cent, were type III, while type I and type II infections to-

Group IV*	211	35	54	25.6
Total	606	100	185	30.5

*Atypical IIs included with the Group IV cases

the New Haven Hospital during the ten year period from January 1, 1921, to January 1, 1931. The series includes all type III cases treated on the Medical Service during this period, 104 in number, and 18 cases from the Pediatric Service* admitted since September, 1927, the bacteriological diagnosis of pneumonia on the children's wards not having been carried out before then. For the sake of comparison certain features of the pneumococcus type I and pneumococcus type II pneumonias admitted during the same periods have been studied. The

gether numbered 273, or 45 per cent. There were in addition 211 atypical II and group IV cases, or 35 per cent.

The incidence of the type III pneumonias according to age is shown in chart 1. This brings out very clearly the relatively high incidence in the later decades of life. In this series 50 per cent of the cases were 55 years of age or older, while only 15.6 per cent occurred between the ages of 10 and 40. By way of contrast it is shown that the type I and type II cases of this series occurred largely in childhood and early adult life, approximately 50 per cent of the type I cases being under 30 years of age; 87 per cent under 50, while of the type II cases 42 per cent

*I am greatly indebted to Dr. J. D. Trask for the privilege of including the cases from the Pediatric Service.

CHART I Incidence of pneumococcus type III pneumonia according to age, pneumococcus type I and pneumococcus type II pneumonia included for comparison

were under 30, 82 per cent under 50. In as much as the cases under 12 years of age occurred during a period of $3\frac{1}{3}$ years and those of 12 years of age or older during a period of 10 years it is obvious that the number of cases in infancy and childhood should be multiplied by 3 in order to approxi-

mate more nearly the actual age distribution. This correction is indicated on chart I by the figures in parentheses. The corrected percentages for the different age periods are shown in table 2.

The relative incidence of type I, II, and III infections at different age

TABLE 2
Percentile Incidence of Type III, Type I and Type II
Pneumonia According to Age

Age	Type III	Type I	Type II
Birth-9	34.2	47.0	32.0
10-39	12.0	33.0	36.9
40-54	15.2	13.7	24.3
55+	38.6	6.3	6.8

periods is brought out more clearly in chart 2 from which it will be seen that approximately 70 per cent of the cases over 60 years of age were type III while only 5 to 17 per cent of those between 10 and 40 years of age were type III cases

The incidence according to sex showed a preponderance of males at all ages, there being 80 cases in males, 42 in females The incidence according to race showed nothing significant, there being 44 Americans of British ancestry, 20 of Irish descent, 14 of the Hebrew race, 12 Italians, 8 Scandinavians, and 5 Germans The remainder were of miscellaneous origin

Incidence and mortality according to months is presented in chart 3 Type III pneumonia does not appear to differ from that due to other types

of pneumococci in its seasonal distribution, the great majority of the cases occurring between October and May, with a very low incidence during the summer In this series the mortality was higher during the fall and early winter than during the spring

PREDISPOSING CAUSES

The rôle of acute predisposing causes immediately preceding the onset of type III pneumonia was very high in this series and apparently played an important part in the etiology of the disease at all ages This is shown in table 3 As would be expected, the acute respiratory infections were outstanding and served as the predisposing cause in 52 per cent of the 115 cases in which information was obtained. Severe exposure, exhaustion and acute

alcoholism also played a considerable part, being recorded as etiological factors in 20 cases. In all an acute predisposing cause was present in 87, or 75 per cent of the 115 cases.

Cecil, Baldwin, and Larsen⁴ called attention to the frequency of chronic diseases in persons who contract type III pneumonia. An analysis of our cases (table 4) amply confirms this. Seventy-nine of the 119 cases in which observations were available, were subject to chronic disease. This might be expected in the patients over 50 years of age, all but 8 of whom suffered from one or more chronic diseases. Of particular interest, however, is the fact that 19 of the 32 patients between 20 and 50 years of age had chronic diseases, 12 with pregnancy are included, and of these, 12 died, while of the 13 in good health only 2 died, one with influenzal and pneumococcus type III pneumonia, the other of a complicating hemolytic streptococcus infection. To what extent chronic disease acts as a predisposing cause is perhaps uncertain, but that it is an important etiological factor there would seem to be little doubt. Particularly significant is the fact that 32 patients in the series suffered from fairly severe, chronic, pulmonary disease, including bronchial asthma, 5, chronic bronchiectasis, 1, chronic bronchitis usually with emphysema 25, and advanced tuberculosis 1. Arteriosclerotic vascular disease, often with heart disease and some degree of heart failure, was present in 39 cases, severe, chronic alcoholism in 11, syphilis in 7, diabetes in 4, and miscellaneous conditions in the remainder. That chronic disease plays an important role in the high

mortality of type III pneumonia seems unquestionable. This relationship will be discussed in a subsequent paragraph.

CLINICAL COURSE

The symptoms of onset and the clinical course of type III pneumonia as exhibited in this series of cases showed no conspicuous differences from those found in the other types and will be presented quite briefly. The onset was sudden in 78 cases, the initial symptom or combination of symptoms being chill in 50, pleural pain in 65, vomiting in 31, and convulsions in 4. In 44 the onset was gradual. There was a definite relation between the method of onset and age in that the onset was much more frequently sudden in patients between 10 and 50 (31), than in young children and those over 50 (151). (Table 5)

The clinical course of the disease presented no unusual characteristics. Sixty-five cases showed pneumonia in one or more lobes of the right lung, of which 34 per cent died, 27 cases showed left-sided involvement, of which 37 per cent died, and 30 cases showed bilateral pneumonia, of which 73 per cent died. (Table 6)

The duration of the disease in uncomplicated cases varied from 1 to 16 days in those that recovered, over 50 per cent having recovered by the eighth day or earlier; from 4 to 12 days in the fatal cases, 50 per cent having died by the sixth day or earlier and 77 per cent by the seventh day. The relation of age to the duration of the disease and the method of recovery in non-fatal, uncomplicated cases is of interest. (Chart 4) In the period of lowest incidence and presumably there-

CHART 4 Duration of disease and method of recovery in uncomplicated, non-fatal cases of pneumococcus type III pneumonia C = crisis, L = lysis

fore of greatest resistance, i e., between 10 and 30 years of age, the cases were clinically mild, of relatively short duration and recovered invariably by crisis. In the two periods showing a somewhat higher incidence and presumably greater susceptibility, i e., from birth to 10 years and between 30 and 50 years, the duration was somewhat longer and approximately half of the cases recovered by lysis. In the period of high incidence and relatively high susceptibility after the age of 50, the disease was of still longer duration and recovery by crisis very rarely occurred. In fact, after 60, the average duration in 17 cases was 10 days and no case showed a critical recovery. A

glance at chart 4 will show that one should be very hesitant about predicting an early recovery by crisis in patients over 30 with type III pneumonia.

Three factors bearing directly on the debatable question concerning the virulence of type III pneumococcus for man, namely, the frequency and degree of bacteremia, the frequency and severity of pneumococcus complications, and the mortality, are of special interest.

The frequency of positive blood cultures in this series is shown in chart 5 and is compared with the frequency of bacteremia in the type I and type II pneumonias in the series. In the fatal cases bacteremia was consistently less

CHART 5 Relative incidence of bacteremia in pneumococcus types I and II pneumonia and pneumococcus type III pneumonia according to age

frequent in the type III infections than in the Is and IIs. Even more striking is the fact that the frequency becomes progressively lower with advancing age in the type III cases while the reverse is true with the Is and IIs. After 40 only a little over one-third of the fatal type III cases showed positive blood cultures while over 80 per cent of the Is and IIs had bacteremia. A similar contrast is presented in the non-fatal cases, a positive blood culture occurring only once among the type III cases, while positive cultures occurred with considerable frequency in the Is, occasionally in the IIs. It is probable, of course, that the considerable number of type I cases with positive blood cultures who recovered was influenced by serum treatment and that some of the type I pneumonias would otherwise have fallen in the fatal group. At any rate it is quite clear that type III pneumococcus invades the blood relatively infrequently, positive cultures being obtained in only 21, or 18.1 per cent of the 116 cases of type III pneumonia in which cultures were made as contrasted with 71 cases, or 36.6 per cent, with positive blood cultures in the type I series, and 32, or 40.5 per cent, in the type II.

The degree of bacteremia as well as the frequency was relatively slight in the type III infections. In the 21 cases showing positive blood cultures, the 45 cultures made showed 13 with no growth, 9 with growth in broth only, no colonies occurring on the pour plates, 14 with 1 to 10 colonies per cubic centimeter of blood, 5 with 11 to 32 colonies, and only 4 (in 3 patients) showed evidence of a heavy septicemia with more than 100 colonies

The time of invasion of the blood in the fatal cases is shown in chart 6, first in relation to day of disease in 45 cases in which the day of onset was definitely known, secondly, in relation to days before death in 53 of the 54 fatal cases, no blood culture being made in 1 case. The number of cultures per patient varied from 1 to 5. It is quite clear that bacteremia in the type III pneumonias of this study was in large part a late or terminal invasion rather than an early one.

The occurrence of complications shown to be due or presumably due to pneumococcus infection was not unduly frequent,—otitis media in 5 of the children, empyema in 1 child and in 4 adults, empyema and pericarditis in 1 adult, pericarditis and endocarditis in 1 adult, and thrombophlebitis in 1 adult. Other complications were staphylococcus suppurative parotitis, 1, cystitis (*B. coli*), 2, acute nephritis, 2, pyelonephritis, 1, non-suppurative arthritis, 1, and complicating hemolytic streptococcus infections, 5.

It has been shown in table 1 that the mortality in the series of type III pneumonias was 44.3 per cent, a figure closely comparable to that reported by others. That this high mortality is apparently not due to a highly virulent organism that invades the blood either early or frequently in the disease, nor to an undue prevalence of complications of pneumococcal origin has been brought out. Consequently other explanations must be sought. The first and most obvious reason is that a very large proportion of type III pneumonias occur in the later decades of life. The relation of age to mortality in this series is shown in chart 7, the

figures for the type I and the type II pneumonias being included for comparative purposes. From this data it is at once obvious that in the same age groups type II pneumonia had an equivalent or higher mortality than did type III pneumonia. Furthermore, the

mortality of type I pneumonia, even with serum treatment in the adults, was equivalent to that of type III pneumonia up to the age of 30 and approached it after the age of 45. There would seem to be little doubt from these results that the total high mor-

CHART 6 Bacteremia in fatal pneumococcus type III pneumonia in relation to day of disease and to day before death. Solid columns represent number of positive blood cultures, unshaded columns number of negative blood cultures.

tality shown by type III pneumonia is due in large part to the greatly preponderate incidence of the disease in the older age groups, rather than that it is due to an organism of particularly high virulence

The relation of chronic disease to the high mortality in type III pneumonia has been touched upon above and will be discussed now in more detail. In the first place it will be seen by reference to table 4 that 40 of the 119 cases in which data were available showed no evidence of chronic disease. Of these

only 6, or 15 per cent died, even though 13 of them were over 40 years of age. Of the 6 that died, 1 had a diffuse bronchiolitis (*H influenzae*) and focal pneumococcus type III pneumonia following whooping cough, 1 really died of agranulocytic angina with a terminal type III pneumonia, 2 had influenzal pneumonia with diffuse bronchiolitis, and 1 died of a complicating hemolytic streptococcus infection which developed 5 days after apparent recovery from the original type III pneumonia, thus leaving only one patient, a man of

CHART 7 Mortality per cent in pneumococcus type I, in pneumococcus type II, and in pneumococcus type III pneumonia according to age

59, who died of an uncomplicated type III infection on the ninth day of the disease

Of particular interest is an analysis of the 9 fatal cases occurring under 40 years of age. The youngest patient was an infant under one year of age with pneumonia following whooping cough. The next was a boy of 14 with agranulocytosis, who developed a type III pneumonia 48 hours before death. The leukocyte count was 1000, with 4 per cent polymorphonuclear cells. The blood culture was positive. The next was a woman of 26 in the ninth month of pregnancy who contracted influenza which was complicated by pneumococcus type III pneumonia. She died on the sixth day. The blood culture was positive. The next was a woman of 31 who had suffered from chronic sinusitis and severe bronchial asthma with chronic bronchitis and emphysema for over a decade. She contracted pneumonia following an acute cold, was admitted on the fourth day of her illness and died on the fifth. The leukocyte count was 35,000, the blood culture negative. The next was a woman of 35 with exophthalmic goiter and syphilis with probable aortitis. She was admitted in a moribund condition and died within 36 hours. The leukocyte count was 58,000, the blood culture negative. The next was a woman of 37 in the third month of pregnancy who had been "sick for two weeks" before the onset of pneumonia. She was admitted on the third day and died on the seventh. The leukocyte count was 19,600, the blood culture negative. The next was a man of 39, a chronic alcoholic with arteriosclerosis and a

fairly marked secondary anemia. Red blood cell count was 3,300,000. Following a "bad attack of grippe" and getting soaked in a rain storm, he developed pneumonia. He was admitted on the second day and died on the seventh. The leukocyte count was 21,400, the blood culture negative. The next was a man of 39 with marked arteriosclerosis. Following a cold he developed pneumonia. He was admitted on the second day with a leukocyte count of 16,200 and a negative blood culture. He developed a marked leukopenia and positive blood culture on the fourth day and died on the fifth. The last was a woman of 39, showing no evidence of chronic disease who had severe influenzal pneumonia with diffuse bronchiolitis. She was admitted on the sixth day with a leukocyte count of 8,800 and a positive blood culture. She died on the ninth day. To continue further with the older patients would be mere repetition and serve no purpose. In order to emphasize the rôle of chronic disease in influencing mortality in this younger group it should be stated by way of contrast that only 4 of the 28 patients who recovered, showed evidence of chronic disease—rickets in a child of 3, chronic nephritis in a boy of 13, bronchial asthma in a boy of 20 and chronic bronchiectasis in a man of 37.

SUMMARY

A consecutive series of 122 cases of pneumococcus type III pneumonia admitted to the New Haven Hospital during the ten year period from Jan. 1, 1921 to Jan. 1, 1931, has been reviewed. Confirmatory of previous reports, it has been found that the inci-

dence is greatest in the later decades of life, approximately 50 per cent of the cases being over 55 years of age. Males were nearly twice as numerous as females. There was no special racial susceptibility found. The monthly incidence corresponded to that of pneumonia in general.

Acute predisposing causes played a very important part in the etiology of the disease, being of undoubted significance in 75 per cent of the cases. The most frequent predisposing causes were the acute respiratory infections—common colds, grippe, and influenza. These immediately preceded the onset of the pneumonia in 52 per cent of the patients. Exposure, exhaustion and acute alcoholism were recorded in 17 per cent. Chronic disease existed in 66 per cent of the patients and in all probability exerted a significant influence on susceptibility. Chronic pulmonary and vascular diseases, and chronic alcoholism were predominant.

The onset, the clinical course and the symptomatology of the disease were similar to those of other forms of pneumococcal pneumonia. In young adult life in otherwise healthy individuals the disease ran a mild course with early critical recovery. In the later decades the disease ran a more prolonged course and recovery by crisis was the exception.

Pneumococcus complications were of the usual frequency. Empyema occurred six times, pericarditis twice and endocarditis once. Otitis media occurred five times in children.

In spite of the high mortality bacteremia was found in only 18.1 per cent of 116 cases, in only 37 per cent of the fatal cases. In the latter it occurred mostly as a terminal invasion 24 to 48 hours before death. In only three cases was a high degree of bacteremia encountered.

Although the total mortality in this series was high, 44.3 per cent, it is shown that this was largely determined by the factor of late age incidence and by the prevalence of chronic disease at all ages in those who succumbed. In 40 cases not subject to chronic disease and irrespective of age, the mortality was only 15 per cent, while in 79 patients suffering from chronic disease (including 2 with pregnancy) the mortality was 56.9 per cent.

Finally, it may be concluded on the basis of the data here presented that pneumococcus type III pneumonia is a highly fatal specific infectious disease due, in general, not to a highly virulent organism that attacks and kills a healthy host, but rather to a debilitated, sickly or senescent host that succumbs to what is a relatively mild and uncommon infection in the young and vigorous.

Tularemic Pneumonia*†

By H H PERMAR, M D, and W W G MACLACHLAN, M D,
Pittsburgh, Pa

THE literature concerning tularemia became fairly extensive following the publication by Francis^{1,2} (1925-1926), of general articles on the subject, and especially after the papers of Francis and Callender³ (1927), of Goodpasture and House⁴ (1928), of Francis⁵ (1928), and of W M Simpson⁶ (1928). The latter articles contributed particularly to the knowledge of pathology of the disease. No attempt will be made here to review the history of tularemia, nor to discuss the literature, save as it concerns tularemic lesions of the lung. The papers of W M Simpson^{6,7} (1928-1930), contain excellent summaries of the more recent literature.

The case from which the materials were obtained for this study is, we believe, the twenty-fifth fatal case to be reported in this country, and the ninth to come to autopsy. A peculiar acute pneumonia was the outstanding finding.

CLINICAL HISTORY

The patient was a negro, aged 36, whose last employment had been in cleaning rabbits

*From the Departments of Pathology and Medicine of the School of Medicine, University of Pittsburgh, and the Pathological Laboratory and Medical Service, Mercy Hospital, Pittsburgh, Pa.

†Read before the Cleveland Meeting of the American Association of Pathologists and Bacteriologists April 2, 1931.

for market. On Monday, November 18, 1930, he cleaned a large number of rabbits and the same evening became nauseated and much fatigued. He was forced to leave his work on the following day as he was severely nauseated, although he did not vomit. He was dizzy and very weak. Later in the day he had a chill, was feverish and had a severe headache. He went to bed and remained there in this state until brought into the hospital on Saturday, November 23, 1930, the fifth day after the onset of symptoms.

On admission the patient appeared to be very toxic, the temperature was 105°F, the pulse 100, the respirations 28. There was some soreness in the right axilla but no enlarged glands were felt. A number of small, superficial cuts were noted on the palmar surface of the right hand, but there were no ulcers. The lungs were clear, although the case was considered at first as a possible pneumonia. The heart was normal. The blood pressure was 120/80, the pulse rate was relatively slow. The spleen was not palpable. The white cells were 7,125, with polymorphonuclear leucocytes, 47 per cent, large lymphocytes, 22 per cent, small lymphocytes, 23 per cent, large mononuclear leucocytes, 8 per cent. The urine was not remarkable. The blood culture was negative. On account of the history of contact with rabbits, blood was sent to Dr Edward Francis at Washington shortly after admission (seventh day of the disease), and the report was, "No agglutination with *B. tularensis*." The subsequent points of interest in the clinical course were as follows: delirium which was almost constant, incontinence of urine and feces, and continued high fever, with relatively slow pulse and respiration.

rates No cough or sputum was present although the patient said he spat up a little blood during the first few days of illness. There were no physical signs of pneumonia until two days prior to death (fifteenth day of the disease), when signs of consolidation were noted on the right side anteriorly, over the upper lobe. Hiccough was very persistent. The Wassermann test on the blood was negative. A later blood count (seventeenth day of disease) showed only 5,200 leucocytes, with polymorphonuclear leucocytes, 84 per cent, lymphocytes, 14 per cent, large mononuclear leucocytes, 2 per cent. There was no subsequent lymph-node enlargement, and on the seventeenth day of his disease blood was again sent to Dr. Edward Francis, who reported a positive agglutination (1-320) with *B. tularensis*. The patient died on the seventeenth day of his illness.

Autopsy

The outstanding autopsy findings were confined almost entirely to the lung, though typical tularemic lesions were also found in the peribronchial lymph-nodes and in the liver. The external appearance of the body offered nothing, save that the palms showed a few healing scratches. The axillary glands were not palpable.

Thorax. The thorax showed voluminous lungs and some pleural adhesions. There was only a slight acute pleural exudate, largely confined to the involved right lung, and chiefly to the right upper lobe, the site of the pneumonia.

The left lung weighed 350 gms, and the right, 950 gms. The lungs presented pleural adhesions, anthracosis and, in both apices, small old tuberculous scars. Both had some edema and congestion, especially in their lower lobes, and more intense in the right lung, the upper lobe of which felt firm and solid. The pleural surface of the right upper lobe was dulled by a film of yellow opaque fibrin, beneath which the interlobular divisions were evident as slightly elevated yellowish lines. On section, the tissue was generally consolidated, though the exudate was much denser along the bronchial tree, especially about the bronchioles and along the interlobular septa. The latter could be seen as opaque lines and they were most evident

in the peripheral parts of the lobe. Some of these lines were quite wide, and so edematous as actually to appear spongy or cystic in the gross. The bronchi, especially the smaller branches, were surrounded by dense, opaque, yellow-white, necrotic-looking areas which merged with the usual black peribronchial markings of anthracosis. The necrotic peribronchial foci were connected by consolidated lung which varied in color and consistency, but which in general had the gross character of gray hepatization. The bronchial tree contained a mucopurulent material that appeared thicker in the finer bronchioles. The larger vessels were clear. Thrombi were not seen on gross examination. The peribronchial lymph nodes showed slight enlargement and marked anthracosis. Their important lesion consisted of small white nodules of necrosis, with no fibrosis about them. There was also in one of the nodes a small area of caseation surrounded by fibrous tissue and showing a little calcification. No other nodes in the thorax or abdomen were found enlarged or similarly involved. The heart and pericardial sac revealed nothing abnormal. The aorta showed only a few superficial fatty streakings.

Abdomen. The peritoneal cavity had no abnormalities. The liver weighed 2,050 gms, and was the only abdominal organ showing notable change. Five or six tiny, pin-head sized, gray-white areas were found beneath the capsule, with neither fibrosis nor congestion about them. They had a depressed surface and appeared as small, clearly marked foci of necrosis of the liver substance, this appearance was borne out on cross section. No additional nodules were found on the cut surface of the liver. These lesions in the liver resembled those in the peribronchial lymph-nodes. In addition, the liver and kidney had undergone definite cloudy swelling. The spleen was congested and showed a typical recent white infarct.

The brain was not examined.

The heart's blood was sterile. No cultures were made from the lung. Direct smears showed moderate numbers of polymorphonuclear leucocytes, many mononuclear cells, often containing carbon granules, and much amorphous debris. No bacteria of any type could be demonstrated in the smears by

ordinary methods, and Ziehl-Neelsen stains showed no acid-fast organisms. No animal injection of tissues was done. The serum obtained on the seventh and seventeenth days of illness was injected into guinea pigs by Dr. Francis, with negative results.

Microscopical Findings

The microscopic changes in the lung, peribronchial lymph-nodes and liver were of particular interest. These organs all showed miliary foci of necrosis, identical with those found in animals and in acutely fatal human cases.

The sections of the involved portion of the lung presented typical miliary necrotic foci in the interstitial tissues. Certain of these lay in the walls of lymphatics, though as a rule they were simply scattered in the

stroma about the bronchial tree and vessels. The interstitial tissues were also the seat of an intense acute inflammation, characterized by extreme edema with much fibrin formation and a cellular exudate made up chiefly of large mononuclear leucocytes. The alveoli were extensively and diffusely involved in a pneumonia of serous and serofibrinous type. The predominating cell in the alveolar exudate was again the large mononuclear leucocyte. These cells tended to crowd the alveolar spaces and to become degenerated and necrotic, and the alveoli containing necrotic exudate also showed numbers of polymorphonuclear leucocytes. The characteristics of the mononuclear phagocytes which everywhere predominated in the cellular exudate were worthy of note. In the edematous interstitial tissues, in the

FIG. 1. Typical acute miliary tularemic lesion of liver.

dilated lymphatics, and in the adventitial and subendothelial zones of the vessels, they had generally a smaller size, with hyaline cytoplasm and a 'clock face' arrangement of the chromatin in the relatively large, eccentric nucleus. In a word, many resembled plasma cells, though all gradations could be found between these and typical mononuclear phagocytes. When they appeared free in the alveoli they were greatly enlarged, with foamy, vacuolated cytoplasm and relatively smaller nuclei that were often pyknotic. In the alveoli their phagocytic properties were most evident. They nearly all contained fragments of chromatin, lipid materials, degenerating erythrocytes, and varied quantities of carbon granules. The alveolar lining cells were swollen and quite prominent in the alveoli containing serous fluid and few inflammatory cells. They were less evident

where the exudate was more massive. It did not appear that the alveolar epithelium had desquamated to any appreciable degree.

Areas of necrosis of large groups of alveoli were a distinctive feature of the pneumonia. The necrosis involved the alveolar walls as well as the contained exudate. This change was the result of a striking lesion, involving both venules and arterioles and consisting of an acute inflammatory reaction of the subendothelial connective tissue with marked edema and swelling and an infiltration by mononuclear leucocytes. This, of course, resulted in great narrowing of the lumina, and as thrombosis tended to occur in many of the narrowed vessels, extensive necrosis of the lung tissue was inevitable. A similar but less marked change was present in the adventitia. These vascular lesions

FIG. 2. Miliary necrotic tularemia foci in wall of bronchus. Note interstitial edema and inflammatory exudate.

were found only in the lobe showing pneumonia

The bronchial tree itself was affected particularly in the finer branches. Here the lumina contained masses of exudate like that in the alveoli, made up of mononuclear leucocytes, coagulated serum, fibrin and polymorphonuclear leucocytes. This exudate showed a tendency to necrosis, as did that in the alveoli. The mucosal linings of some of the bronchioles showed localized acute inflammation and even necrosis, which appeared to be a progression from the miliary necrotic foci in their interstitial tissues. It was noted that the mucosa of the larger bronchi revealed much less injury and exudate. The inflammatory reaction in the interstitial tissues was the outstanding feature of the reaction, while that in the bronchial tree was a

minor one, occurring by direct extension from the wall into the lumen.

The sections of the small focal liver lesions and of the similar but somewhat larger necrotic lesions of the peribronchial lymph nodes presented the characteristic acute necrotizing process that has been described by Verbruyck⁸, Francis and Callender³ and others, and therefore does not require elaboration here.

The infarct of the spleen gave the typical microscopic picture of a white infarct. This was in all likelihood the result of embolism from a pulmonary thrombus. No vascular lesions like those in the pneumonic lung were found in the spleen or other organs.

Fat stains (Sudan III) demonstrated moderate amounts of neutral fat in fine globules in the wandering mononuclear cells

FIG 3 Extreme edema of stroma with fibrinous and mononuclear cellular exudate and serous exudate in alveoli

of the exudate, notably in the necrotic exudate. This was true in all the tularemic lesions, whether in lung, liver, or lymph nodes at the hilus of lung, but the striking fatty changes described by Palmer and Hansmann⁹ were not evident in the other organs. Controlled Ziehl-Neelsen stains on lung tissue showed no acid-fast organisms. Gram-Weigert and Giemsa stains for bacteria in the lung tissues revealed no organisms. The Brown-Brenn stain, which is especially useful for Gram-negative bacteria, showed no Gram-negative organisms, and no evidence of secondary infection.

DISCUSSION

The literature contains published reports of eight autopsies on fatal tularemia. In Francis' case¹⁰, the chest was

not prosected, though there was clinically a pneumonia. Verbrycke⁸ reported in the lungs typical acute tularemic nodules, the size of small shot, and one the size of a walnut. These had an associated bronchopneumonia in adjoining alveoli and bronchioles. Bardon and Berdez¹¹ described small necrotic patches involving several alveoli. The septal walls were necrotic. The necrosis resembled that of tuberculosis. Palmer and Hansmann's⁹ case presented what they termed an "inconsiderable" bronchopneumonia, but they noted unusual numbers of vacuolated mononuclear cells in the smaller vessels and wan-

FIG. 4. Mononuclear phagocytic cells in the alveolar exudate.

dering into the alveoli. Bunker and Smith¹² found a marked bronchopneumonia, with extensive necrosis of the alveolar walls as well as of the free exudate. The cellular exudate consisted chiefly of polymorphonuclear leucocytes, though many lymphocytes and endothelial cells were present. The peribronchial lymph-nodes in all the foregoing were reported as showing typical tularemic granulomatous foci, in either the acute or the sub-acute stage. W. M. Simpson's⁶ case, the most acute to come to autopsy, had no pneumonia, but two typical

acute tularemic nodules were found in the lung tissue. The case of Goodpasture and House¹ showed only a localized pleurisy with a mononuclear cell exudate, near the enlarged peribronchial lymph-nodes. In Bruecken's³ case (in which the patient had recovered from a pneumonia in the early weeks of the disease), the lungs were found clear at autopsy when death from chronic glandular tularemia finally occurred five months after the onset.

In brief then, seven out of the eight cases in which the thorax was prosected (87.5 per cent) presented

FIG 5 Subendothelial edema and mononuclear cellular exudate in intima of pulmonary vessel. Serous and fibrinous exudate in adjoining alveoli with necrosis of lung tissue and the contained exudate.

tularemic lesions of some type in the lung; and in five of the eight (62.5 per cent) there was diffuse pneumonic involvement. Of all the reported fatal cases, now numbering twenty-five, nine (36 per cent) showed pneumonia either clinically or at autopsy.

The present case report indicates that an infection by *B. tularensis* occurred without demonstrable localized granulomatous ulceration on the skin and without regional lymphatic involvement. In the absence of peripheral localized tularemic lesions in either

the skin or lymphatics, one must consider here the possibility of primary respiratory tract infection, with direct interstitial invasion of the lung. The mode of infection of the lung cannot be determined from the data available, but the case is of value since it gives an opportunity to describe in detail the pulmonary lesions.

The presence in the stroma of the lung of the typical miliary necrotic focal lesion is the most significant single finding, from the standpoint of identifying the pneumonia as of tulare-

FIG. 6. Thrombosis of pulmonary vessel showing subendothelial edema and mononuclear cellular exudate. Necrosis of the surrounding lung alveoli and the contained serofibrinous exudate.

mic origin. The other outstanding feature is the extreme subendothelial edema and mononuclear cellular infiltration in the blood vessels. This latter observation has not been recorded previously. It is of considerable interest, as we believe this vascular lesion with the associated thrombosis in the affected vessels, explains the peculiar necrosis that has been noted in tularemic lung inflammations. The usual proliferative and obliterative changes in the smaller vessels and capillaries, which were first described in tularemic lesions in the human by

one of us (Permar and Weil¹³), and subsequently by Francis and Callender³, and others, are not present, probably because of the rapidly fatal course of the disease. The predominance of mononuclear leucocytes in the cellular exudate is evident in this case, as in most of those previously described.

We believe that we have demonstrated a pneumonia with morphologic changes which are presumably specific for tularemia and recognizable with reasonable certainty in the absence of a suggestive history or of a positive agglutination test. It is of course to

FIG 7. Small bronchiole with a mononuclear cellular exudate. A more active process present in the surrounding lung tissue.

be kept in mind that the duration of the disease may well alter somewhat certain phases of the microscopic reaction. Further, we are not aware of a pulmonary inflammation occurring in any other infectious disease that has exactly the characters described here.

As to the clinical importance of lung involvement in tularemia, we agree with Francis^{5,14} who has stated that a pulmonary lesion indicates a serious prognosis. This is borne out by the high incidence of pneumonia in fatal cases. We would emphasize that the history of contact with carriers of *B. tularensis* (most commonly wild rab-

bids), is very important in the diagnosis and further, that the agglutination test is necessary for absolute confirmation. It must be kept in mind, as indicated by this case, that a positive agglutination test may not be developed early in the disease.

SUMMARY

The case of tularemia which forms the basis of this report was remarkable in that there was neither a peripheral ulcerative lesion nor regional lymphadenitis. The outstanding clinical manifestations were a markedly toxic state and an atypical pneumonia.

FIG. 8. Large bronchiole with the wall intact, and containing a little serous exudate and a few mononuclear phagocytes.

Tularemia was suggested by the history of handling dead wild rabbits and was confirmed by a positive agglutination test for *B tularensis* on the patient's blood serum

At autopsy, the gross findings in the lung were unusual, indicating an acute lobar pneumonia with much interstitial inflammation and necrosis. The lesion suggested an acute diffuse reaction of granulomatous type.

The histopathologic lesion was essentially an interstitial pneumonia, distinguished by multiple miliary necrotic foci throughout the stroma of the diseased lobe. These necrotic foci were identical with those seen in an acute diffuse tularemic infection. An intense and widespread inflammatory edema accompanied the development of the specific tularemic nodules in the lung. The blood vessels of the affected lobe showed great edema of the subendothelial and adventitial connective tissue, with an infiltration of mononuclear leucocytes into these coats. This involvement of the vessels produced much narrowing of their lumina, and complete occlusion by thrombosis was often found. Areas of necrosis of considerable size and irregular outline

were a striking feature of the microscopical findings. This necrosis was associated clearly with the vascular lesions just described, and appeared to have been caused directly by the vascular narrowing and occlusion.

Thus it may be stated that when a diffuse pulmonary involvement occurs in the course of a tularemic infection, the prognosis must be grave, as acute tularemic inflammation of the lung is a progressively destructive lesion. This is borne out by the data available on fatal tularemia.

The authors take pleasure in availing themselves of this opportunity to express their thanks to Doctor John M. Johnston of Pittsburgh for his kind assistance in the preparation of the microphotographs illustrating this paper.

Since this paper was written, the authors have learned from Dr. Edward Francis of the Public Health Service, National Institute of Health, Washington, D. C., that four other autopsy reports, two with prominent lung lesions, are in process of publication, and Hartman of Detroit reported before the American Association of Pathologists and Bacteriologists, April 2, 1931, an autopsy on tularemia with interstitial tularemic pneumonia among the findings. These cases add somewhat to the evidence that pulmonic tularemia has a grave prognosis.

Experimentally Produced Lesions of the Liver*†

By JESSE L. BOLLMAN, M D, and FRANK C. MANN, M D,
Rochester, Minnesota

MANY problems of clinical medicine have been clarified by experimentation on animals. This method has numerous advantages in that most of the factors which enter into the production and progression of abnormal processes are capable of exact control. Although it is not as yet possible exactly to simulate in animals all of the types and phases of hepatic disorders, it is possible to produce experimentally most of the abnormal conditions usually associated with hepatic disease in human beings. With our associates we have studied a large number of animals following various procedures which have directly affected the liver, and it is from these animals that we have drawn our conclusions concerning the physiology and pathology of the liver.

Perhaps our most valuable data have been obtained from animals following complete removal of the liver,^{2,4,6,7,9,11,12,14,15,20,21} but since most of the facts of this series are well known, only brief mention of them will be given here. After proper preliminary measures to eliminate complicating factors

such as portal stasis, the liver may be completely removed and the signs of complete hepatic insufficiency may be observed. Because the liver alone adds glucose to the blood, hypoglycemia is the first definite symptom referable to the absence of the liver. Fortunately, in the human being only the rare case of extreme acute atrophy of the liver presents this symptom. If hypoglycemia is prevented by the administration of glucose the liverless animal presents no unusual symptoms for twenty-four to forty-eight hours, at which time a characteristic set of symptoms develops and death from complete hepatic insufficiency follows. These symptoms are loss of hearing, loss of vision, loss of reflexes, muscular rigidity, coma, convulsions, and death, progressively occurring in the order mentioned, the entire course usually lasts from thirty minutes to four hours. We know of no hepatic disease in which these symptoms are exactly reproduced, although several of them are noted in fatal cases of supposed hepatic insufficiency. In addition to loss of the power of forming sugar, the liverless animal also loses the power of forming urea, of destroying amino acid and uric acid, and of effecting other metabolic changes for which the liver is essential.

*Read at the Baltimore Meeting of the American College of Physicians, March 23 to 27, 1931.

†From the Division of Experimental Surgery and Pathology, The Mayo Foundation, Rochester, Minnesota.

It would appear that any test⁸ capable of measuring the metabolic changes which depend entirely on the liver would give an accurate index of the efficiency of this organ. There are several reasons why such tests show but little, and studies of animals from which the liver has been partially removed reveal some of the reasons for failure of these tests. In the dog, and in many other animals, the liver consists of several distinct lobes, one or more of which may be successfully removed. Immediately following such operations the remaining portions of the liver begin to hypertrophy and by serial operations removing a lobe of liver every few weeks, it is possible to remove more hepatic tissue than was originally present and still have a normal weight of hepatic tissue remaining in the dog. Even the liver of the normal adult dog is capable of restoration of more than 100 per cent of its weight. During this process no signs of hepatic deficiency are observed except a transient upset of a few days duration which probably is due to injury of the remaining hepatic tissue rather than to actual deficiency because of removal of tissue.

It is possible to prevent this restoration of liver following partial removal, and each of the three methods I will describe have their counterpart in most cases of chronic disease of the liver. Restoration of hepatic tissue is greatly reduced or completely absent in the presence of obstructive jaundice¹², in the presence of marked cirrhotic changes in the liver, or when the portal blood supply to the liver has been reduced, as by an Eck fistula¹⁰. When one of these three conditions is present

partial hepatectomy may be performed without subsequent increase in the size of the remaining part of the liver. With these methods animals may be maintained by proper dietary precautions with less than twenty per cent of the normal amount of hepatic tissue. These animals show surprisingly little evidence of decreased hepatic efficiency by any of the functional tests which we have employed. It is obvious that less than twenty per cent of the liver can accomplish the work of the entire organ.

Animals with complete obstructive jaundice caused by ligation of the common bile duct show many signs which are familiar to the physician. For the first few days the liver is enlarged, but it soon becomes smaller than normal, and there is rather extensive atrophy of hepatic cells. Under ordinary conditions the jaundiced dog does well for a few weeks, but after this time many interesting phenomena may appear. In the first place, a diet rich in carbohydrate becomes increasingly more necessary for the maintenance of these animals, we use milk bread, and syrup. After two or three months a diet exclusively of meat, if taken, will prove fatal within about one week, but with a diet high in carbohydrates life may be prolonged for at least a year. Abdominal and esophageal varices develop and hemorrhage into the gastro-intestinal tract is of frequent occurrence. Duodenal ulcer¹¹ occurs in an extremely high percentage of cases. Ascites develops spontaneously in the later periods of obstructive jaundice, and may be produced and relieved experimentally at an earlier period by dietary measure.

Infectious cirrhosis, experimentally produced, is very similar to that rather infrequent type as seen in man. Following experimental cholecystenterostomy¹ there is an ascending infection of low grade involving the biliary ducts. After several months the gross appearance of the liver is not unlike that in the usual type of nodular cirrhosis, and on the cut surface of the liver are seen marked thickening and dilatation of the bile ducts, with marked cicatricial changes. Microscopic examination discloses that the infective process has encroached on the hepatic parenchyma and there is infiltration with leukocytes, and later with round cells. There are definite zones of fibrous tissue surrounding the biliary ducts and in this there are many proliferating small bile ducts which present a picture suggestive of canalization such as that which occurs in a thrombosed blood vessel. Animals with infectious cirrhosis have no definite symptoms until the liver is extensively involved. Gastro-intestinal upsets, diarrhea, vomiting, and occasional melena, are usually the first symptoms noticed. With progression and continued attacks of gastro-intestinal bleeding, definite anemia usually develops, and a small amount of ascitic fluid may be present before death. Jaundice has not been observed, except as a terminal event.

To produce an experimental picture similar to the usual type of portal cirrhosis, it is necessary repeatedly to administer sublethal doses of a toxic agent which produces acute necrosis of the liver. We have used carbon tetrachloride and tetrachlorethane. The latter was extensively used as a solvent

for waterproof aeroplane paint before it was discovered that many workers with this poison contracted subacute yellow atrophy or cirrhosis. The method of administration to experimental animals determines somewhat the character of the lesions produced. If the material is injected into the spleen repeatedly, extensive atrophy of the left side of the liver occurs and there is marked hypertrophy of the right lobes of the liver. Injection of the material by peripheral vein or subcutaneously and also oral administration, is followed by more or less diffuse acute necrosis, with subsequent permanent changes in the liver. These changes also represent atrophy and hypertrophy but are found in close proximity in all portions of the liver. Consequently hypertrophic or atrophic cirrhosis may be produced, depending on the predominance of hypertrophy or atrophy. With increasing injury to the liver these animals have most of the symptoms characteristic of portal cirrhosis. Gastro-intestinal upsets, diarrhea, and intestinal hemorrhage are usually the first symptoms observed, and definite retention of dye may be detected. With continuation of administration of the toxic agent, slight jaundice may be produced, and finally marked ascites may develop. Few of these animals die of actual hepatic insufficiency; many have died following excision of a small piece of liver for histologic examination, a procedure that is relatively harmless to the normal animal. Many die following extensive gastrointestinal hemorrhage, and in many chronic or subacute duodenal ulcer develops, with subsequent perforation and peritonitis. We have lost a large

number of animals following repetition of administration of the toxic agent. The necrosis produced seems to be more extensive as the liver becomes more severely injured, and a picture similar to that of subacute yellow atrophy frequently results. It should be noted that repetition of administration of the toxic agent is necessary, since this type of lesion is not progressive, and the animals improve considerably when the toxic agent is removed.

The chronic lesions of the liver we have been able to produce depend on the acute lesions repeatedly produced. Changes are not observed with frequent doses which are so small that acute necrosis is not produced. If doses that are too large are used, extensive necrosis results, from which the animal does not recover. The extent of acute hepatic injury obviously depends on the amount, toxicity, and specificity of the toxic agent used. In this respect it may be noted that we have been unable to produce hepatic necrosis with alcohol alone, but the addition of alcohol to several toxic substances produced much more extensive lesions. This increased toxicity may be due to the fact that most of these toxins are soluble in alcohol and that the effective dose is greatly increased when they are absorbed with the alcohol. Additional reasons for increased necrosis may be found in the fact that alcohol injures the liver so that it is unable to combat additional poisons. There is considerable evidence that the extent of hepatic injury also depends on variations in the more or less specific resistance of the liver to injury. In dogs much more exten-

sive lesions are produced by chloroform¹⁸ or carbon tetrachloride⁵ when the animals are maintained on a meat diet than if they are maintained on a diet high in carbohydrate and rich in calcium. The difference in activity of the hepatic cell appears to be correlated with the amount of glycogen in the liver and is less when the fat is more predominant. In this respect it should be noted that there is a cycle¹⁹ of changes in the glycogen and fat content of the liver, daily, with relation to the time of meals. Toxic agents are much more effective when administered to the fasting animal than when administered even several hours after the taking of food. Impairment of circulation in the liver increases the effectiveness of many hepatic poisons. After exclusion of the portal blood from the liver by an Eck fistula, carbon tetrachloride is more than ten times as effective as similar doses given to normal animals.

Many animals with considerable necrosis and with fatty changes in the liver show no symptoms, but when necrosis is more extensive, gastro-intestinal upsets, jaundice, and a small amount of peritoneal fluid may be noted. If further toxin is not administered, and if the necrosis is not too extensive, reparative processes begin in a short time. Within twenty-four hours there is marked leukocytic infiltration, and lymphocytes predominate later. The disintegrated hepatic cells appear to be removed by phagocytes, and their place is taken by new hepatic cells which have arisen by division of the adjacent uninjured hepatic cells. There is also a proliferation of fibrous tissue, apparently arising from that around the

portal spaces. Repetition of this process may give rise to extensive scarring of the liver, such as is seen in typical portal cirrhosis. Hypertrophic nodules develop, apparently by division of a few hepatic cells into many cells in a restricted area, so that lobular arrangement is not possible, and these islands of hepatic cells show little relationship to the blood vessels and biliary ducts of the liver.

In general, it may be said that the reparative processes of the liver tend to restore that organ to normal appearance, and it is surprising to see that after extensive injury, restoration of the liver may be so effective that the organ appears quite normal. Continual repetition of the process, however, gives rise to cirrhosis in which the size of the liver depends on the predominance of hypertrophy of the hepatic cells, or their absence due to the extensive cicatricial changes.

Our observations on experimental animals may be summarized best by considering those processes which in general appear to affect the response of the animal to the alterations in pathologic changes in the liver. One of the most striking observations, already referred to, is that the liver possesses huge reserve as evidenced by the extreme amount of liver that may be injured or removed without the production of any symptoms referable to the liver. Actual removal of as much as eighty per cent of that organ is not attended by a measurable loss of hepatic function, and sufficient liver remains to enable the animal to carry out all of its normal life and to appear to be well. In addition to the fact that less than twenty per cent of the normal

liver is necessary, the liver is capable of more than 100 per cent replacement due to the restoration of tissue. These observations appear to offer a definite explanation for the fact that the classical signs and symptoms of cirrhosis do not appear until the liver has been almost completely worn out by the repeated attacks of some toxic agent. It is to be noted, also, that the three factors which prevent restoration and repair of the liver in the experimental animal are each present in cirrhosis, that is, more or less extensive cicatrization of the liver, reduction of the actual blood supply to the liver, and jaundice. That cirrhosis is not entirely a hopeless condition, however, appears from the observation that animals with extensive cirrhosis, ascites, and jaundice do not continue to progress downward, but recover from their symptoms when the toxic agent is removed and a diet high in carbohydrate is administered.

The development of collateral circulation in the experimental animal appears similar to that found in the human being. In extensive cirrhosis from toxic agents, obstructive jaundice of long duration, or uncompensated extensive removal of hepatic tissue, the veins of the entire portal region are found to be dilated, and varicosities develop in the esophageal veins and in the abdominal wall. Hemorrhage into the gastro-intestinal tract is of frequent occurrence, but massive fatal hemorrhage is less common. Most animals with extensively injured livers have tarry or bloody stools and definite anemia. This intestinal bleeding is seldom continuous, usually it occurs in attacks lasting from two to ten days.

after which there are spontaneous remissions of short duration. In some animals a subacute or chronic duodenal ulcer develops from which hemorrhage may occur. Studies of the blood of these animals fail to show any definite alterations in the known factors concerned in coagulation. It is obvious that the control of coagulation is less stable than normal when the liver is extensively injured. Values for blood fibrinogen and blood platelets may at times be found to be low, but later, in the same animal, may be normal. Coagulation time and clot retraction time are likewise variably found to be delayed or normal. Obviously, other factors affect the coagulation of the blood in addition to the definite, although vague, influences of the liver. That the hepatic factor, however, plays a definite part in the hemorrhages, is evidenced by the fact that we have never observed this type of bleeding in dogs prepared for removal of the liver in three stages. In this method both the vena cava and the portal vein are occluded below their entrance into the liver and there is extensive collateral circulation sufficient to return both caval and portal blood to the heart, the liver is only slightly injured, if at all, and bleeding or a change in the factors of coagulation does not occur. Recovery of animals from extensive hepatic injury is accompanied by recovery from this hemorrhagic tendency, although the collateral circulation may not appear to be altered.

Since a small amount of hepatic tissue is sufficient to maintain the normal functions, both metabolic and excretory, of that organ, it does not appear surprising that most functional

tests fail to indicate hepatic pathologic changes until they are extensive. Many of the metabolic tests which have been devised are influenced by the previous diet and the condition of the other organs of the body, as well as by the condition of the liver. This is particularly true of a number of tests devised to determine the activity of the liver in carbohydrate metabolism, and some of these we have found to give similar results when applied to a normal animal as to one completely deprived of its liver. Tests based on the activity of the liver in the metabolism of protein give the anticipated results in entire absence of the liver but deviation from normal is not appreciable in cases of hepatic injury unless the injury is extreme. In most of our experiments on rapidly failing animals failure of protein metabolism was present, and usually the fatal termination ensued in a few days. Quantitative estimation of the detoxicating power of the liver, particularly with salicylates, camphor, compounds of phenol and so forth, have not been satisfactory in our hands. We have distinct evidence that many of these compounds are conjugated partially or completely in the entire absence of the liver. The guanidine¹⁷ content of the blood may be definitely elevated in the presence of acute intoxication with extensive hepatic necrosis, but it rapidly returns to normal without giving any indication of the amount of permanent injury to the liver.

Tests designed to evaluate the excretory function of the liver appear to be the most satisfactory of any hepatic tests we have used. Failure of this function is indicated by bilirubinemia,

this is not observed in the experimental animal without biliary obstruction unless extensive hepatic injury is present. Acute hepatic necrosis is usually accompanied by bilirubinemia of a degree approximately parallel to the extent of the hepatic injury. In acute and chronic hepatic injury, the van den Bergh reaction is direct. Extensive lesions of the liver also produce definite delay in the excretion of bilirubin and other chromogenic substances which may be injected intravenously. We have recently determined the retention of bromsulphthalein in a series of dogs with varying degrees of experimentally produced cirrhosis. Several tests were made prior to surgical exploration and biopsy, and several tests were made after this procedure, before additional carbon tetrachloride had been administered to produce more extensive cirrhosis. In each animal the degree of retention of dye was compared with the gross and microscopic appearance of the liver. For the most part, there was very satisfactory correlation between the degree of injury to the liver, as estimated from the gross appearance and histologic section, and the degree of retention of dye. There were, however, exceptions in sufficient numbers to demonstrate clearly that the last word is yet to be said regarding the function of the liver and its pathology. A few animals with extensive cirrhotic changes, usually hypertrophic, gave no evidence of retention of dye, although few normal-appearing hepatic cells could be demonstrated histologically. A few normal animals, with no demonstrable hepatic lesions, gross or microscopic, showed marked retention

of dye. It should also be mentioned that a few livers, which microscopically appeared to be definitely cirrhotic, appeared grossly to be normal.

Ascites develops spontaneously in animals with very extensive cirrhosis, and also following obstructive jaundice of long duration. Under both of these conditions we have been able to produce and remove ascitic fluid by dietary measures. Animals with obstructive jaundice were maintained for three or four months on a diet of milk, bread, and syrup and showed no evidence of ascites. They were then fed meat for three or four days. In most animals the presence of ascites could be determined by inspection of the abdomen within twenty-four hours after the feeding of meat was instituted. It was not uncommon for the abdominal circumference of an animal weighing five to seven kilograms to increase from an original measurement of about 35 centimeters to more than 50 centimeters, and from one to three liters of fluid could be aspirated from the peritoneal cavity. In many animals this process was repeated several times. Certain animals appeared more resistant than others, but in all ascites developed within four days of the initiation of repeated feeding of meat. In a few experiments the animals refused to eat meat in any form, and feeding by stomach tube was not very successful. Most of the animals that were refractory to formation of ascitic fluid became less so as the interval following complete biliary obstruction increased, and with repetition of the regimen of meat feeding. As the process was repeated more and more ascitic fluid could be formed with small

ler and smaller intake of meat. Experimental cirrhosis must be very extensive before ascites can be produced in this way, but if the cirrhosis is extensive enough feeding of meat will produce ascites.

The active substance which produces ascites in these animals is probably not

liters of newly formed ascitic fluid can be withdrawn. Control experiments with the addition of salt to the diet have produced entirely negative results.

The ascites disappeared in most instances when the meat or the meat extract was withdrawn from the diet.

FIG. 1. Atrophy and hypertrophy of the liver. In the upper row are the lobes of a dog's liver three years and three months after a series of injections, lasting three months, of small amounts of carbon tetrachloride into the spleen. In the lower row are the lobes of a normal liver of the same weight removed from a normal dog of the same size. Hypertrophy of the right lateral lobe and atrophy of the other lobes may be noted. This condition is not changed from that seen at exploration two and a half years previously.

protein. Proteins of milk do not favor the production of ascites. The active principle appears to be in the water-soluble extractives of meat. The feeding of meat extract which is free from protein and fat produces results which are even more striking than the feeding of meat. Within four to six hours after feeding twenty-five grams of meat extract to animals with obstructive jaundice of long duration, or with extensive cirrhosis, marked abdominal distention is evident and two or three

The substitution of large amounts of carbohydrate to the diet seemed to aid in the removal of the fluid; the fluid disappeared more rapidly than when all food was withheld. With repetition of the formation and removal of ascitic fluid, the animals became more susceptible to accumulation of fluid, and the time of disappearance of the fluid with the feeding of glucose became greater and greater. The mercurial diuretics, given in small doses, were also effective in reducing the as-

cites, but these too became less effective after several administrations. Transfusion of blood into those animals with ascites that showed definite evidence of anemia, and in some instances, also, definite reduction of the values for plasma protein, were effective in removal of ascitic fluid. Transfusion was not effective in the animals with ascites if these changes in the blood were not present. In all of our experiments the progressive loss of resistance to the accumulation of ascitic fluid was accompanied by increased in-

jury to the liver, either by the increasing duration of biliary obstruction or by continuation of administration of carbon tetrachloride.

The mechanism by which meat extract produces ascites in these animals is not understood. In the animals in which it does produce ascites there does not seem to be any alteration in the control of peritoneal fluids prior to the administration of the extract. If saline solution or ascitic fluid, either from dogs or men, is injected into the peritoneal cavity of dogs, it is absorbed

FIG 2 Experimental cirrhosis from carbon tetrachloride. The liver of a dog which had received 100 doses (5 cc each) of carbon tetrachloride over a period of two years.

as rapidly by animals which are in the pre-ascitic stage as by normal animals. It would appear that meat extract might produce ascites by one of three possible mechanisms, none of which is proved (1) because of a specific colloidal effect on the blood or vessels which enables water to diffuse into body cavities more readily than

normally, (2) a specific effect on the liver, which produces constriction of the intrahepatic portion of the portal system with subsequent sufficient increase in portal pressure to produce vascular changes in the abdominal viscera, or (3) specific irritation of the peritoneal surfaces, which increases the secretion of fluid from these surfaces

Fig. 3. Hypertrophic cirrhosis with subsequent atrophy. Size of the liver of dogs with peritonoperitoneum, *a*, normal animal of the same weight and size as that illustrated in *b*, *c* and *d*, *b*, marked hypertrophy which occurred in one year in which the animal received 150 cc. (1 cc. each) of tetrachlorethane, *c*, same animal as that shown in *b* sixteen days later, *d*, same animal as that shown in *b* and *c* after twenty-eight more days. Additional tetrachlorethane is not given and within three months the liver had returned to normal size.

and inhibits their absorption of fluid. It is to be noted that in any case, extensive injury to the liver must be present, so that it appears obvious that a normal liver must compensate for, or detoxify, this active agent which will produce ascites when the liver is extensively injured.

In all of our experimental work, the proportion of carbohydrate in the diet of animals with extensive hepatic lesions is of outstanding importance. In the entire absence of the liver, animals succumb to hypoglycemia unless glucose is given. We have maintained dogs with complete biliary obstruction for six to twelve months on a diet of milk, bread, and syrup, and have repeatedly observed the rapidly fatal effects of diets composed entirely of meat. After biliary obstruction has been present for three months we have

been unable to cause a dog to survive on a diet entirely of meat for more than six days. The protective value of carbohydrates against hepatic injury from toxic agents is well illustrated by the following experiment.

Four dogs were maintained on a diet of milk, bread, and syrup, and four on a mixed diet, containing about 25 per cent meat protein, 50 per cent carbohydrate, and 25 per cent fat, four other dogs received as much meat as they desired. All of these animals received daily doses of 10 cc of carbon tetrachloride by mouth. At the end of one month, one of the animals that was fed meat had marked ascites and died two weeks later. Within three months ascites developed in one of the remaining animals, which later died, and the other two meat-fed animals were distended with ascitic fluid. In the same period of three months, the other eight dogs remained in good condition and showed no signs of ascites. Biopsy revealed that the livers of the animals to which meat had been fed suffered more extensive injury than was

FIG. 4. Hypertrophic cirrhosis, specimen removed from dog the day the roentgenogram shown in figure 3 b was taken.

present in the other animals, although lesions with the definite appearance of cirrhosis were present in all

Glucose is of definite value following surgical procedures on animals with extensively injured livers. Following operation, these animals are markedly lacking in resistance, and extensive degenerative changes rapidly occur in the injured liver. Intravenous injection of large amounts of glucose appears to enable many animals to recover that would almost certainly succumb had the glucose not been given. This same specificity for glucose appears in animals suffering from acute intoxication following excessive administration of hepatic toxins.

SUMMARY

From our experimental studies of animals with definite pathologic lesions of the liver we feel justified in drawing a few general conclusions.

First, because of the extensive reserve and extensive reparative processes of the liver, symptoms of chronic hepatic disease appear as evidence that most of that organ has been destroyed and that the capacity for reparative processes is almost exhausted. In our experiments, however, removal of the agent responsible for the production of hepatic lesions has enabled the animal (and liver) to recover sufficiently to maintain fairly normal life.

FIG. 5. Lobular arrangement of the liver and increased connective tissue in specimen shown in figure 4 ($\times 50$)

Second, a definite tendency toward intestinal hemorrhage is present in animals with extensively injured livers, and this tendency improves as the condition of the liver is allowed to improve, although the distended varices of the collateral circulation remain

Third, ascites in the experimental animal may be controlled by dietary measures

Fourth, diets rich in carbohydrates appear to be essential for the maintenance of animals with extensively injured livers

Further Studies in Allergic Migraine:

Based On a Series of Two Hundred and Two Consecutive Cases*†

By RAY M. BALYCEAT, M.A., M.D., F.A.C.P., and HERBERT J. RINKEL,
B.S., M.D. *Oklahoma City, Okla.*

IN a recent work on the hereditary factor in allergic diseases by one of us¹, it appears that migraine is interchangeable in the linkage with asthma and seasonal hay fever, which is excellent evidence that they have a common etiologic factor, namely, a specific sensitization. That protein sensitization is the causative factor in true bronchial asthma and seasonal hay fever is generally accepted. In a previous study² of allergic migraine a family history of allergy was elicited in 85.4 per cent of all cases. We observed that many asthmatic patients also suffered from migraine. A large per cent of migraine cases studied gave definite reactions to one or more foods and the results of treatment, based on our allergic findings, were equal to those obtained in the treatment of asthma. Our study led us to believe that the exciting factor in probably 100 per cent of true migraine cases is a specific sensitization to one or more foreign proteins.

The data contained in this paper were collected from a review of 202

consecutive cases of migraine examined at our private clinic, of which there were 135 female and 67 males, and from a careful questioning of 198 practicing physicians, 260 medical students, 107 nurses, 845 women teachers, 581 male and 521 female high school students, and 270 unemployed.

We were stimulated to give this subsequent review as we believe we have much additional evidence to substantiate the conclusions drawn from our first study.

AGL AT ONSET

Alger³ finds 3 per cent of migraine cases develop before 10 years of age. Block⁴ states that the vast majority of cases develop symptoms before 25 years of age. Flatau⁵, in a history of 500 cases, shows that in 12 per cent the trouble started before the age of 15. Timme⁶ remarks that adolescence is the chief time of onset. Of our series of 202 cases, 60, or 29.7 per cent gave a definite history of onset of symptoms before they were 10 years of age. An additional 30.6 per cent manifested symptoms before 20. The fact that 60.3 per cent of all migraine develops before 20 is significant in our theory as to etiology, which will be discussed later is correct.

†From the University of Oklahoma Medical School and the Balyceat Hay Fever and Asthma Clinic, Oklahoma City, Okla.

TABLE I
Distribution of age at onset of clinical manifestation of migraine in patients of all ages,
based on 202 cases

Age at Onset	No of Cases	Per Cent
First decade	60	29.7
Second decade	62	30.6
Third decade	50	24.7
Fourth decade	25	12.3
Fifth decade	3	1.4
After fifth decade	2	.9

In ascertaining the history of onset of migraine from adults many will answer the question as follows "As long as I can remember", or "About the time I started to school, as I remember the teacher would send me home from school on account of my headaches and vomiting" We are caring at present for a number of cases of migraine under 5 years of age, most of whom came not on account of the headaches but for relief of some other allergic syndrome We have a few cases whose symptoms did not appear until after 40 Organic brain lesion, however, should always be thought of in one developing headache at this age

INCIDENCE OF MIGRAINE

No reference has been found in the literature to the frequency with which this symptom complex occurs Business men, society women and students are reported to be more subject to the syndrome than other people That migraine is more common in women

than men is frequently mentioned As a means of trying to determine the number of people who suffer with typical attacks of migraine, we interviewed personally, or (with the assistance of Dr H H Cloudman, chief physician to the Oklahoma City Public Schools, through a detailed questionnaire) obtained data concerning the history of migraine in 2,728 individuals

It appears from the above findings that migraine is about twice as common in the female as in the male, and that it occurs twice as often in doctors and male high school students as in unemployed male laborers We have always contended that migraine, like other allergic diseases, occurs in those with a highly developed vegetative nervous system, therefore the percentage in the unemployed laborer should be much less, and according to our findings it is Considering the fact that the incidence of migraine is nearly 4 per cent in the indigent male labor-

TABLE II
Incidence of migraine in different classes of people

	Total No	No with Migraine	Per Cent
Physicians and medical students	101	31	29.9
Students	107	13	12.1
Unemployed male laborers	270	10	3.7
Women laborers	845	88	10.4
High school students, male	581	39	6.7
High school students, female	521	71	13.5

ei, and about 10 per cent in the student and business class, a conservative estimate would place the percentage in people at large at about 7 per cent. Considering the age of onset and the disappearance of symptoms we estimate the number of people in the United States who now suffer from the syndrome at approximately 4,000,000.

From table II it can easily be seen that migraine is more common in business men, professional men, and teachers, than in other people. For example, we found that 79 per cent of all physicians and medical students gave a history of typical migraine, 104 per cent of all women teachers suffer from the disease, while less than 4 per cent of the indigent laboring men suffer from the symptom complex.

An answer to the question as to why migraine is more common among business men, professional men, and teachers, than in farmers, factory workers, and the indigent laboring class, is not easy. We wish to offer the following explanation as a possible answer. In a study of 1,217 patients with asthma and hay fever one of us¹ showed that the general health of allergic patients is far above the normal, and in the study of the mental activity of allergic children, we⁷ found 75 per cent were either in the superior, very superior, or genius class, which is far above the average. From our study of those who suffer from migraine it appears that they follow the rule of other allergic patients in regard to general health and also mental activity. One who has the ability to become specifically sensitive and suffer from some allergic condition has a highly developed vegetative nervous system.

Such a system is a prerequisite for a good business man, professional man, teacher, etc. The boy on the farm, or the one who comes from the laboring class, who inherits a highly developed vegetative nervous system, soon learns that he is a good student and enjoys his school work. He then becomes a university student. Therefore, from these children come our professors, doctors, lawyers, preachers, bankers, society women, etc. In other words they naturally drift into the part of society where they belong.

SYMPTOMATOLOGY

Not unlike asthma, the frequency of migraine headache varies greatly. Some patients suffer once a week, others every two or three weeks or every two or three months. The average frequency in our series is one attack in three weeks. Some patients are never entirely free from a slight headache between attacks. The duration of the attack again varies greatly, ranging from 12 to 96 hours. The average duration in our cases was 30 hours. In some instances a remarkable periodicity is noticed, especially in women who have attacks just before or during the menses. Again, like asthma, migraine may disappear during pregnancy.

Typical attacks of migraine consist of *First* a prodromal stage; *second* aura, *third*, attack, *fourth* post-migrainous symptoms.

The *prodromal stage* in our series was characterized by a period of depression with nervousness and irritability. In 26 per cent, 19 per cent stated that they felt unusually well the day previous to the attack, but many were

noted in 23 per cent; and 53 per cent gave a history of a druggy or profound sleep the night preceding the headache.

The *aura* was manifested by faintness or vertigo in 21 per cent; scintillating scotomata in 81 per cent; hemianopsia in 22 per cent, and photophobia in 38 per cent. Auditory and olfactory symptoms were complained of by 4 per cent and 3 per cent respectively. Paresthesia of the hands occurred in 81 per cent; of the feet in 37 per cent; and of the face in 18 per cent. Motor symptoms were manifested by motor aphasia in 44 per cent, paresis in 0.6 per cent. Vasomotor disturbances were complained of in 7 per cent and mental confusion was reported or observed in 31 per cent.

The *attack* consisted of hemicrania at one time or another in 94 per cent of all cases studied, while the remaining 6 per cent never experienced pure hemicrania. A unilateral headache which became generalized was noted in 49 per cent. Nausea occurred in 73 per cent; emesis in 65 per cent. Pyrexia has been observed in some of the children during an attack.

Post-migrainous symptoms consisted of exhaustion in 40 per cent of our cases, polyuria in 6 per cent, rhinorrhea in 9 per cent, and a tendency toward sleepiness in 18 per cent.

We have observed a change from the typical migraine attack in a number of patients in the late 30's and early 40's. The headache became chronic, less severe, and usually generalized. The symptoms of the aural stage are usually less marked, nausea persists, but emesis is rare.

In children the headache may be severe, but it is usually milder than

in adults. Gastric symptoms are much more common and severe in children than in adults. The so-called cyclic vomiting in children is probably migraine. Like asthma and other allergic symptom complexes, one may live under exactly the same environment, on a routine diet, and yet for some reason either lose his attacks entirely or have them milder for a period of years, only again to resume them in their original severity. Migraine frequently disappears in the late 40's in both men and women, but many continue to suffer throughout the 50's and early 60's.

THE HEREDITARY FACTOR IN MIGRAINE

That heredity is the most potent factor in the production of migraine is not questioned. Timme^a states that 50 per cent show this characteristic and that the mother transmits the disturbance in 75 per cent of the cases. Hassin^b says "heredity is most important in considering the cause of migraine. It may be direct (migraine in parents) or indirect (various other nervous or mental disorders in the family)." Both Timme and Hassin are neurologists and have studied the subject from a neurological standpoint. Neither mentions the possibility of a specific sensitization as an etiologic factor, or the relation that exists between migraine and the well established allergic syndromes. In studying many of the family trees in our series we have been impressed with the fact that the disease is interchangeable in the linkage with the well established allergic syndromes, namely, asthma, seasonal hay fever, perennial hay fever, urticaria

and certain forms of eczema and colitis. It appears that it is only one of a number of syndromes which are metamorphosed in passing from parent to offspring. For example, five children in one family might be specifically sensitive to wheat. From such a sensitivity asthmatic symptoms might appear in the first child, eczema in the second, hay fever in the third, urticaria in the fourth, and migraine in the fifth. The mother of these five children might have been a hay fever sufferer due to the Russian thistle pollen and her mother have had asthma due entirely to a specific sensitivity to cat hair. The specific state is not inherited, but only the ability to become sensitive.

Four family trees are being offered to show the relation between migraine and the other allergic syndromes. In the pedigree shown in chart 1 you will note that the patient suffers from migraine and urticaria, that the father of this patient also suffered from migraine, but his sister had asthma, and the paternal grandmother had asthma, one of her sisters had asthma, and one brother suffered from asthma, but there is no record of migraine in her immediate family. The patient's son is also an asthmatic. In other words, in one generation asthma appears, in the next generation some of the children have asthma, others migraine, in the third generation migraine and urticaria, in the fourth, migraine only.

The family tree as shown in chart 2 is of interest as we find a patient with migraine, who has one brother and one sister with migraine, and whose mother had migraine. He has one son with hay fever and asthma. This son

has a newborn son. In all probability this newborn will not develop migraine, hay fever or asthma, but may develop a sensitivity to food and have eczema, urticaria or colitis.

In chart 3 we find a patient who suffers from epilepsy of a type that is definitely sensitive to food and has been controlled by food elimination. She has one sister with asthma and one with epilepsy. The sister with epilepsy has not been treated, but she has a child who has asthma. Our patient's grandmother had migraine, one maternal aunt had migraine, and one asthma. Her great grandmother had migraine and her great grandmother's sister had asthma. Here we find migraine transmitting epilepsy and in turn epilepsy transmitting asthma. Some of the neurologists have tried to show us that migraine is very closely associated with epilepsy. We have not found it so. We believe that those epileptics whose family history is saturated with migraine should be thoroughly studied from the standpoint of food sensitivity as a cause of their epilepsy.

Our patient as shown in chart 4 has migraine, asthma and eczema, and this is not an uncommon finding. He has a sister with asthma, his father had migraine, one paternal aunt with urticaria, one with migraine, and his paternal grandfather had asthma. The paternal grandmother had migraine and eczema. More than three-fourths of all migraine cases that we have studied suffer from other allergic diseases.

From the four cases presented and many similar ones we have studied it appears that migraine is interchangeable in the linkage with asthma, hay

CHART 4 Showing that migraine cases can have other manifestations of allergy

fever, urticaria, and certain types of eczema, colitis and epilepsy. This observation, along with the clinical findings that 81.1 per cent of all of our cases suffer from other allergic syndromes is excellent evidence that the etiology is the same, namely, a specific sensitization to foreign protein.

Our patients and we inherit from the same germ plasm and therefore the same plans and specifications are used in our make up, which accounts for our having traits in common. We inherit only a hypersensitive cellular make up.

In some cases there seems to be a definite tendency to become sensitive to certain atopic groups, as has been pointed out by Coca⁸. Some patients apparently become sensitive to atopic substances in food with ease compared to other groups. Others develop a sensitivity to pollen with similar ease, others to animal dander, etc. The fact that a fair number of eczema, urticaria and migraine patients are comparatively negative to the inhalant group of atopic substances, both by testing and clinically, is striking. In other words, it appears that some patients may become allergic to one or more foods early in life and have eczema, urticaria or migraine, but never become sensitive, or if so to a sufficient degree, to the inhalant groups, in spite of the degree of contact, to develop asthma or hay fever. One of us⁹ has pointed out the fact that the massiveness of the contact dose has much to do with determining the atopic substance to which the patient will become sensitive.

We have also shown¹⁰ that a food sensitivity usually manifests itself in

the form of eczema, asthma or perennial hay fever rather early in life. We naturally would therefore expect migraine, if the etiology be that of a food sensitivity, likewise to appear at an early age, and from our findings it actually does.

In this series of cases a positive familial history of migraine or a family history of the well accepted allergic diseases, was elicited in 167, or 82.1 per cent. There were 145, or 71.3 per cent, with a unilateral family history and 23, or 11.4 per cent, with allergic histories on both sides of the family. Of those with a unilateral family history the trait was transmitted through the mother in 112 or 55.4 per cent and through the father in 57, or 28.2 per cent, of the cases. The figures relative to the transmission of the disease through the female do not correspond to those frequently quoted. Span and Cooke¹¹ found a positive antecedent history in 58.4 per cent of a series of 462 cases of bronchial asthma and hay fever studied. Rowe¹² reported the occurrence of allergy in the antecedents in a series of bronchial asthma in 56.4 per cent. We¹³ reported a series of 1,000 cases of asthma and hay fever in which there was a positive antecedent history of allergy in 60.1 per cent, a series of 188 cases of urticaria with a family history of allergy in 67.6 per cent, and a series of 181 cases of eczema, in which a definite familial history of allergy was present in 64.3 per cent of the cases.

It appears from our findings previously given in this paper that an antecedent history of allergy is found in as great or a greater per cent of patients who suffer from migraine

than in those who suffer from asthma or hay fever. The fact that migraine is interchangeable in the linkage with asthma and hay fever and that there is a family history of allergy in as great or greater per cent of cases than in the well established syndromes leads us to believe that they have a common etiologic factor.

PREDISPOSING FACTORS

Like asthma, there are many conditions which play a part as predisposing factors. Consideration should be given the following:

- (1) Physical fatigue,
- (2) Mental fatigue and depressed states,
- (3) Thyroid dysfunction,
- (4) Genito-sexual,
- (5) Toxic states,
- (6) Disturbance of the special senses.

Typical attacks of migraine may follow exhaustive physical exertion, prolonged worry, extreme depression, or, in women, occur just previous to or at the menstrual period. Endogenous toxins, such as from infected teeth, tonsils, or toxins from an exogenous source, such as partially burned gas fumes, may bring on headache. Refractive errors, or a disturbance of the normal hearing, smelling, seeing or tasting may play a part in precipitating an attack. The various factors just mentioned must be considered not as basic ones but predisposing only. In many of our cases after the food to which they were specifically sensitive was removed from the diet they remained free from their usual migrainous attacks. At the time of the menstrual period, physical fatigue, thyroid

dysfunction, toxic state, or disturbance of the special senses, as the case might be. We are inclined to believe that the stress and strain of life as a predisposing factor has been very much overestimated, since 29.7 per cent of our cases had typical migraine before 10 years of age and an additional 30.6 per cent before 20. In these cases the stress and strain of life surely had little to do with their symptoms.

ETIOLOGY

Over a century ago it was suggested by some French investigators that migraine, asthma, hay fever, eczema, urticaria, and epilepsy, might be of similar origin. In 1890 and again in 1900 Haig¹⁴ wrote rather extensively concerning migraine, in which he felt that an increase in uric acid was the chief cause. The disease received but little investigation until the last decade. Pagniez¹⁵ in 1920 treated the syndrome by the use of peptone on the assumption that it was anaphylactic in origin. Ball¹⁶ reported a series of 20 cases treated with peptone and states that clinically migraine is associated with asthma, hay fever, urticaria, epilepsy and therefore he believes that it is due to a hypersensitiveness to food. In 1927 Vaughan¹⁷ studied 33 cases from an allergic standpoint. This seems to be the first series of migraine cases to be carefully tested for a food sensitivity and their treatment based on such findings. Vaughan was the first to show that patients sensitive to food or foods could be partially or wholly relieved by specific avoidance, and that an attack of headache could be produced by the ingestion of the specific food. Later in the same year Row mentions four patients with migraine

who obtained great relief on diets based on the elimination of the foods to which he found them sensitive. In 1928 Rowe¹⁹ states that food allergy must be considered a possible cause of all cases of migraine. In 1930 one of us² reported a series of 55 cases studied from the standpoint of protein sensitization. Treatment of these cases consisted of eliminative measures based on positive food findings. The cases were studied primarily for the purpose of determining the exciting factor or factors. It was concluded from this small series that the exciting factor in probably all cases is a specific sensitivity to one or more food proteins. Recently Eyermann²⁰ has reported a study of 63 cases in which he showed that many cases could be freed from their headaches by elimination of the foods to which they are sensitive, and then headaches could be produced by deliberate partaking of the specific food. Recently in reviewing the histories of 100 cases of asthma in the adult we found that 20, or 20 per cent, had associated with their asthma typical migraine. In other words, it appears that the symptom complex is more common in allergic than in nonallergic people. Beckman²¹ has suggested a disturbance of the acid-base balance as an etiologic factor in allergic diseases. R and S Weissmann-Netter²² found the hydrogen ion concentration and alkali reserve normal in the migraine patient in periods of freedom from attacks but a tendency for alkalosis to develop 48 hours prior to an attack. It is believed by many that carbohydrates have much to do with precipitating an attack. Zinsser²³ states that carbohydrates are non-antigenic sub-

stances, therefore they could not be the exciting factor but might act as a predisposing factor.

The present series of 202 cases under consideration includes the 55 previously reported. In our study of the last 147 cases the intradermal method of testing for food sensitivity has been employed much more extensively. In every case studied a reaction to one or more proteins was found. We use the scratch method of testing routinely but this is always followed routinely by the use of the intradermal method. It has been our experience that a large percentage of the foods do not react to the scratch test and the intradermal method therefore is necessary to find all food factors. If a question arose as to a reaction being of a nonspecific origin passive transfer was employed. Of the cases studied, 70, or 34.2 per cent, suffered from asthma, 98, or 48.5 per cent, had hay fever, 41, or 20.3 per cent, had eczema, 35, or 17.3 per cent, had urticaria, and 14, or 6.9 per cent, had colitis. In the series we naturally found many sensitive to the inhalant group of atopic substances. During the last year all cases have been tested with allergens made in our own laboratories, which have been tested clinically for potency. Any food or any combination of foods, may cause migraine, but the following foods, as etiologic factors, are of importance in order as they are numbered.

- (1) Milk,
- (2) Wheat,
- (3) Eggs,
- (4) Nuts.
- (5) Beans.
- (6) Fish.

Multiple sensitization to food is very much the rule. Frequently, however, one food may be of primary importance clinically. We have learned that a one plus reaction to a particular food may be much more important than a four plus reaction to some other food.

PATHOLOGY

Little has been written on the pathology of migraine. Church and Peterson²⁴ remark, "In the absence of any known morbid changes we must fall back on theories and analogies."

An acceptable theory of migrainous pathology must take into consideration the frequency in early life, the influence of the vegetative nervous system, and the frequently recurring condition which leaves no permanent organic change that may be demonstrated in histologic study. Endarteritis is not an acceptable theory because approximately 60 per cent of the migraine patients will suffer before the second

decade. Further, the pathologic theory must explain the multiple cortical manifestations; namely, scintillating scotomata, hemianopsia, paresthesias, motor aphasia, paresis and occasionally auditory or olfactory auras. One patient presents the following symptoms in order named: paresthesia of the right finger, progressing up to the shoulder, then scintillating scotomata, followed by hemianopsia, motor aphasia, mental confusion, with the headache on the left side, and with subsequent nausea and vomiting. The headache may become generalized, or remain localized, or pass down into the upper cervical region. What is the most likely histopathogenesis of these symptoms? It seems somewhat improbable for this to be due to vasospasm. The isolated and definite areas affected do not correspond to the arterial supply of the cortex. Rackemann²⁵ states that the possibility of cerebral vascular spasm, as shown by Cobb and his associates,

CEREBRAL LOCALIZATION OF COMMON MIGRAINE SYMPTOMS

Motor and sensory areas of vasomotor dilatation seem to explain best the symptoms of localized cerebral vasospasm complained of by those who suffer from migraine.

makes it proper to consider migraine on a pathological as well as on a clinical basis as related to other allergic manifestations. With the vasomotor spasm theory we cannot agree. We believe that there is ample evidence to classify migraine as allergic, and therefore we see no reason why one should consider the pathology of migraine as differing from the typical pathological lesion of other allergic diseases, namely, local edema. In urticaria we have a lesion characterized by primary dilatation of the blood vessels of the cutis, followed by an exudation of fluid into the tissues with cellular infiltration. Hansel²⁰ has described in detail the allergic reaction of the nasal mucosa. In all of these allergic manifestations there is a marked pathogenic similarity. In view of this fact, why should we consider that the allergic reaction within the cortex is different histopathologically from other allergic reactions? It is reasonable to assume that the attack is due to a sudden dilatation of the vessels of the cerebral cortex instead of a spasm. The fact that about 15 per cent of the patients can obtain freedom from their headaches by the use of epinephrin or ephedrine is evidence in favor of this theory. Until more convincing evidence is presented we see no reason to assume that the allergic pathogenesis differs in migraine from any of the other allergic diseases.

The question naturally arises as to why the local dilatation of the vessels of the cerebral cortex of the brain should occur, and not in other structures of the body. It appears that the French experimenter Arthus²⁷, may have explained this phenomenon. He observed that the mechanism of

anaphylaxis, for example, in the rabbit differed from that of the guinea pig, but only in the site of the reaction. In the rabbit, the site of the occurrence of the reaction is in the muscle of the arteriole of the lung. The arterioles are constricted completely so no more blood can pass through. The blood pressure falls completely and the animal dies. In the guinea pig the site of the reaction is in the muscle of the bronchiole. In the dog the site of this reaction is in the liver. Thus, the site of the anaphylactic reaction due to the same foreign protein in one animal might be in the muscle of the bronchiole, in another in the muscle of the arteriole of the lung and in the third, in the liver. Anaphylactic and allergic reactions are not the same, but similar in many respects. Clinically one patient may be sensitive to wheat and have asthma due entirely to the sensitization to that specific food, another have no symptoms of asthma whatsoever but have hives, the third patient manifest symptoms of perennial hay fever due to a wheat sensitivity and the fourth patient local symptoms in the brain, namely, migraine due entirely to a sensitivity to wheat. In other words, a sensitivity to the same food may manifest itself in producing edema of the mucous membrane of the bronchial tree in one individual, giant urticaria in another, a congestion of the nose in the third and in the fourth a local edema in some part of the brain. From a study of experimental anaphylaxis in the animal and clinical manifestations of allergy in the human it seems logical to believe that the migraine patient has a localized edema of the brain due to a specific sensitization.

to food in a similar way to that in which urticaria cases have localized edema of the skin, or asthmatics have localized edema of the bronchial *cul de sac*. After the local edema of the bronchial tubes, a hive on the skin, or a patch of eczema disappears, the area involved will show no structural changes. Likewise in an autopsy on a patient who has suffered from severe migraine for a number of years, no pathological changes can be detected.

DIAGNOSIS OF MIGRAINE

The direct diagnosis of migraine is based upon a history of familial headaches and in the majority of the cases a history of other allergic manifestations either in the antecedent who has the sick headaches or his blood relatives. It is aided by the history of other allergic manifestations in the individual and the direct history of paroxysmal recurrent sick headaches that started early in life, and manifested by a chain of symptoms which in the typical case is characterized by four stages—the prodromal, the aura, the attack, and the post-migrainous phase. During the prodromal stage the patient is either depressed or hyperactive and many note bulimia or a druggy sleep. Following the prodromal state the patient may develop the typical headache without preceding aura. Sensory symptoms are the rule. The most common sensory symptoms are scintillating scotomata, photophobia, hemianopsia (usually homologous), and paresthesia of the hands, feet or face. The majority of these sensory symptoms are contralateral to the hemicrania. Motor symptoms occur in approximately 50 per cent of

the patients, motor aphasia being the most common.

In a small percentage of the patients there may be mental confusion. Vasomotor symptoms are fairly common and may occur before the headache appears or during its course. In some cases there is flushing, in others pallor, or there may be general profuse perspiration. Occasionally we note inequality of pupils.

The headache, or third stage, develops as a rule along with some of the sensory or motor aura, but as stated above may develop without any preceding sensory or motor symptoms. It varies in degree and location but in the great majority of the patients it is a hemicrania, and in approximately 50 per cent of the patients it starts as a hemicrania and becomes generalized. At one attack the headache may be a pure hemicrania and in a subsequent attack start as a unilateral headache and become generalized. Along with the headache the patient usually develops nausea, which may or may not be followed by emesis. As a rule emesis is more common in the early years of the headache.

The duration of the attack may extend from a few hours to several days, may alternate from side to side, and as the headache wears off the patient passes into the post-migrainous stage characterized by exhaustion, sleepiness, polyuria, or nasal irritation.

The direct diagnosis of migraine is established when relief is obtained by removing specific foods from the diet and symptoms recur on deliberate partaking of these foods. It is preferable that these foods be removed and added without the patient's knowledge.

Physical findings are more valuable to rule out the presence of other conditions than to establish the direct diagnosis. The laboratory findings in the typical case will be of little value in confirming the diagnosis of migraine. Testing by the scratch and intradermal methods will reveal positive reactions to various foods or other foreign proteins in practically 100 per cent of the cases.

DIFFERENTIAL DIAGNOSIS

All cases of migraine are cases of headache, but not all cases of headache are migraine. The syndrome must be differentiated from functional headache, trifacial neuralgia, myalgia intoxications, such as those of alcohol, tobacco and uremia, and from headache due to a brain tumor or pituitary dysfunction. As a means of differentiating migraine from pituitary headache Engelbach²⁸ states

"The diagnosis of pituitary headache, however, cannot be made upon the characteristic location, severity of pain and associated ocular or gastric symptoms. There must be sufficient other evidence of pituitary disorder, such as osseous, genital, dermal or pigmentary changes, accompanying these headaches to warrant such a diagnosis."

Tierney²⁹ states

"our cases of pituitary headache have been more often found in individuals with other signs of pituitary disturbance, have been bilateral, nonparoxysmal, associated with different ocular manifestations, if any, and not usually accompanied by nausea and vomiting"

Migraine associated with vomiting is not uncommon. More than one patient with migraine has lost his normal appendix due to a mistaken diagnosis. A clear cut history of periodic headache occurring since childhood or young

adult life, with perfect freedom between attacks, especially if there is an ancestral history of allergy, spells migraine. A differential diagnosis of cases in which the headache is of recent origin is more difficult. The average physician probably would not think of migraine as a diagnosis in a child coming with a complaint of periodic headache. In all probability the child would be sent to the oculist or rhinologist for investigation. Even the pediatrician frequently forgets that migraine is common in childhood.

About 50 per cent of our cases developed migraine before 15 years of age. About 7 per cent of all people have migraine sometime in life. In other words, at least 2 per cent of all children during the first decade suffer from migraine. In making a differential diagnosis a family history of allergic conditions should be given much weight. One should be careful of making a diagnosis of migraine however, in one whose symptoms appear after 40 years of age unless the family tree is filled with allergy. Migraine, like other allergic diseases, is not always typical. In an atypical case with a family history filled with allergy one would probably not err in making a diagnosis of migraine. On the other hand, if the symptoms are not clear cut and there is no definite family history of allergy, one is not justified in making such a diagnosis.

PROGNOSIS

'Timme' states that with few exceptions migraine disappears in the fourth or fifth decade. From our study this appears not to be exactly true since of the 202 cases 22 came

seeking relief during the sixth decade. From the standpoint of life and death prognosis is good. Many patients also have other allergic diseases. It is not uncommon for a patient to have his life seriously interfered with due either to the frequency, or to the severity, of migrainous attacks. Of our cases, 4, or 19 per cent, were not able to carry on a gainful occupation on account of the severity of the attacks, and in 10, or 49 per cent of our patients, their symptoms seriously interfered with their work.

TREATMENT

Treatment should consist of *first*, pre-marital advice, *second*, thorough elimination of predisposing factors; *third*, careful investigation and elimination of the exciting factors; and *fourth*, treatment of the attacks.

Pre-marital Advice It is certainly the duty of a family physician or specialist dealing with migraine to instruct the parents of allergic children concerning the possibility of the transmission of the disease. A young man with migraine who marries a girl with migraine or some other allergic syndrome, or one whose family tree is saturated with allergy, may expect some form of allergy to appear in about three-fourths of his children.

Predisposing Factors Until the last decade much attention was given to the predisposing factors as little was known about the exciting ones. Predisposing factors should be determined and eliminated. For example, plenty of rest and sleep should be taken by the sufferer, avoidance of physical exhaustion and mental fatigue and worry is always in order. Toxic states should be investigated and eliminated if

found. Correction of refractive errors and any error of the special senses should be done.

When all the foregoing measures have been taken many patients will be some better but not until the exciting factors, namely, the foods to which they are sensitive, are found and removed, can one hope for good results.

Elimination of Exciting Factors In our present series of 202 cases, who have been treated by specific food eliminative measures, 44, or 21.7 per cent, received either total, or more than 80 per cent, relief, which we consider excellent results. Another 76, or 37.6 per cent, received between 60 and 80 per cent relief, which we count good results, and another 58, or 28.7 per cent, received from 40 to 60 per cent relief, which we consider fair results. Twenty-four cases had but little or no relief.

From our findings it appears that the results in the treatment of migraine are as good or better than those obtained in nearly any other chronic disease. The average patient who receives more than 80 per cent relief, practically speaking, is well, as the symptoms interfere little with his comfort, the comfort of his family, or his ability to carry on a gainful occupation. Frequently those who receive more than 60 per cent relief are extremely grateful because they realize that their unhappy, uncomfortable, impractical condition has been greatly changed. Diet manipulation based on specific sensitization to food finding seems logical, is practical, and there is no element of danger in it.

Treatment of the Attack For those cases who have prodromal symptoms

appearing the day before the actual attack, manifesting themselves by irritability, nervousness, abnormal appetite, etc., carbohydrates and sugars should be restricted in the diet, a saline cathartic should be given, and but little or no evening meal should be taken. The following morning if the attack actually appears, no breakfast should be taken, and if the stomach will permit, a second mild saline cathartic should be given. The noon lunch should be a light one. Sugars and carbohydrates should be restricted. Some sufferers feel better lying down without too much light in the room.

As many remedies as there are drugs in the Pharmacopeia have been suggested for the relief of pain during the attack and in only an occasional attack do they really do much good. Morphine and codeine should be used as the last resort. Barborka³⁰ has suggested the use of the ketogenic diet. With such a method the patient is kept in a state of ketosis. From an allergic standpoint such a diet in some cases should relieve the patient from symptoms, or partially relieve him, as there would be removed either entirely or in part the foods to which he is specifically sensitive. To keep a patient in a state of ketosis for a chronic disease like migraine seems rather severe, as there is surely an element of danger. An eliminative diet based on a study of the foods to which the patient is specifically sensitive on the whole gives results equal to those of practically any other chronic disease.

CONCLUSIONS

1. Migraine appears to be common in childhood since nearly one-third of

all cases studied developed symptoms during the first decade.

2. The syndrome is more common in business men, professional men and teachers, than in laborers.

3. About seven per cent of all people in the United States sometime in life suffer from the symptom complex.

4. Like asthma, symptoms of migraine in childhood may vary greatly from those of the adult. Gastric symptoms are usually marked.

5. Migraine is interchangeable in the linkage with other allergic syndromes.

6. A family history of allergic diseases was elicited in 167 out of 202 cases, or 82.1 per cent.

7. Of the 202 cases studied 81.1 per cent suffered from other allergic syndromes.

8. From our findings it was concluded that the exciting factor in all cases of migraine is a specific sensitization.

9. There are many predisposing factors which should be investigated and eliminated.

10. The pathology in migraine is probably a local vasomotor dilatation producing a local congestion of the brain corresponding to a hive on the skin.

11. A familial history of allergy or a history of allergic manifestations in one who suffers from headache aids but does not establish a diagnosis of migraine.

12. The treatment of migraine based on allergic findings gives results equal to the treatment of practically any other chronic disease.

Diet As a Factor in the Etiology of Anemia*†

By RICHARD A. KIRN M.D., *Philadelphia, Pennsylvania*

JUST as the body strives to preserve a constant composition of other important factors in the internal environment so, too, the red cell and hemoglobin content of the blood is maintained at a normal level even under very adverse circumstances. When human beings^{1,2,3} or animals⁴ are subjected to prolonged and complete fasting, red cell and hemoglobin figures per unit volume remain at or near normal until long after marked general body wasting has taken place. In partial starvation, when food intake is below body needs, anemia does not occur until very late, provided the diet is reasonably diverse. For example, a hysterical woman, observed in the University Hospital, had in the course of 14 months starved herself to an extreme degree of emaciation yet her blood showed 4,760,000 red cells and 78 per cent of hemoglobin. This is due in part to the careful hoarding and re-utilization of available material (as we know to be the case with blood pigment, and as is perhaps the case with cell stroma), and in part to the fact that the materials necessary for red cell and hemoglobin formation are abundantly present in a great variety

and number of foods. So anemia is uncommon in the rapid wasting of Grave's disease or severe diabetes. (The average red cell count in 100 cases of Grave's disease was 4,610,000, and the hemoglobin, 80 per cent. One patient lost 105 pounds in 12 weeks yet his blood showed 4,600,000 red cells and hemoglobin 90 per cent.) It is safe to say that anemia results from dietary causes only when the diet is greatly restricted as to certain foods and then only when such a diet has been persisted in for a long time.

Much has been learned in recent years of the rôle of diet in blood formation. Especially the studies of Whipple, of Minot, and of their collaborators have demonstrated the quantitative effects of individual foods on red cell and hemoglobin production in various pathologic states. In the light of their findings we are better enabled not only to treat anemic conditions but also to evaluate diet as a factor in their production.

DIET AND SECONDARY ANEMIA

Diet plays its most conspicuous part in the production of secondary anemia. The essential feature is usually a diet poor in iron and other hemoglobin-building foods. While anemia from this cause may occur at any age, there are certain times of life when it is more common. The condition first pre-

*Read before the Baltimore Meeting of the American College of Physicians, March 27, 1931.

†From the Medical Division of the Hospital of the University of Pennsylvania.

sents itself, and with great frequency, in infancy. The normal infant born at term possesses a sufficient store of hemoglobin and non to tide it over the lactation period until a more varied diet meets current blood-building needs. Should the infant have a deficient supply to begin with, or should the inception of mixed feeding be too long deferred, a hypochromic or secondary anemia will result. Pediatricians have, therefore, long recognized that nutritional anemia is most likely to develop in premature infants, in those underweight at birth, in twins, in those whose lactation period is too prolonged or who early develop abnormal eating habits. Abnormalities of gastrointestinal function can further add to the infant's troubles by interfering with absorption. Mackay⁵, on the basis of observations in 770 infants, concludes that the condition is essentially an iron deficiency which is curable by iron medication (iron and ammonium citrate) and preventable by the same means if treatment is started at the age of two months. She finds no evidence of a vitamin deficiency. Hill⁶ reaches similar conclusions but obtained quicker results by combining liver with iron therapy.

Adolescence is the next period in which we often see anemias due to a diet low in iron and in other hemoglobin building foods. Chlorosis is the most marked example of this group, and while other factors are possibly concerned in its etiology, one cannot help but feel that the virtual disappearance of this condition in the last few decades is largely due to the better knowledge of diet and exercise in adolescence. In its place, however,

there are seen an increasing number of chloro-anemias in middle age, chiefly in women, due to a diet low in iron, in meats and vegetables, high in carbohydrates, and aptly called by Minot the "Soda Lunch Diet." To recognize the true nature of these cases clinicians should investigate with greater care than heretofore the diet habits of their patients and, in order to advise them intelligently, should familiarize themselves with the rôle of diet factors in hemoglobin construction as so thoroughly worked out by Whipple and his collaborators^{7,8}.

Lack of vitamins has been suggested as a possible cause of anemia. Here the evidence is as yet meager and contradictory. Experimentally, Happ⁹ found that rats kept for a long period on a diet low in anti-rachitic substance became anemic. Secondary anemia was observed by Sartori¹⁰ in pigeons deprived of vitamin B and in guinea pigs on a diet low in vitamin C, and a pernicious type of anemia by Wills and Mehta¹¹ in rats on diets with no vitamin C and almost no vitamin A. On the other hand, no effects on red cells or hemoglobin were noted by Sherif and Baum¹² in rats deprived of vitamins A, B, C and D, or by Cartland and Koch¹³ in rats deprived of vitamins A, B, and E; or by Sure, Kik and Walker¹⁴ in vitamin B or E deficiency in rats. Clinically, Koessler and Maurer¹⁵ have claimed that 75 per cent of patients with severe anemia give a dietary history of vitamin deficiency, and Aron¹⁶ calls attention to the fact that anemia in children is often associated with scurvy. However, Keffer and Yang¹⁷ and Pillat and Yang¹⁸ in observations on anemia as

ciated with various clinical avitaminoses point out that in the majority of instances the diets of these individuals have been deficient in hemoglobin-building substances as well. It is conceivable, however, that an associated avitaminosis could aggravate the anemia-producing effect of a diet also deficient in red cell and hemoglobin-building materials.

The claim that a copper deficiency may play a part in causing secondary anemia has not been substantiated. Whereas Waddell, Steenbock and Hart¹⁹ found that of 13 metals copper alone, when added to iron, cured anemia in young rats caused by a whole milk diet, Drabkin and Waggoner²⁰ cured such animals by a synthetic diet containing less copper than the original milk diet.

Brief mention is made of a form of nutritional anemia that has attracted considerable attention especially in Germany in recent years. In 1916, Scheltzema^{20a}, and in 1918, Schwenke²¹ independently reported cases of anemia in infants fed on goat's milk and since then numerous similar observations have been recorded. The blood picture is usually that of secondary anemia, but in a considerable minority of cases there is present an anemia pseudo-leukemica^{22,23} with severe anemia, high color index, macrocytosis, nucleated red cells, leukocytosis, pallor and an enlarged spleen, and which Stoeltzner²² refers to as possibly an infantile form of pernicious anemia. The cause of the anemia is not certain. Brouwer²⁴ points out that it is probably not an iron deficiency, for the anemia develops at an age before the infant normally exhausts its iron store. While goat's

milk has been found quite low in vitamin C^{25,26}, the addition of vitamins to the diet is not effective²⁷, and puppies fed on goat's cream and cow's skimmed milk become anemic²⁸. It is, therefore, probably not an avitaminosis. The myelotoxic action of certain fatty acids abundantly present² offers perhaps the best explanation. An unknown constitutional factor has also been invoked²⁹. A change to cow's milk diet is curative.

DIET AND PERNICIOUS ANEMIA

Since Biermer³⁰ in 1872 in his original communication on progressive pernicious anemia expressed the opinion that insufficient and unsuitable food was a factor in its etiology, much has been written of the possible relation of diet to this disease. However, not until the announcement by Minot and Murphy³¹ of the treatment by liver feeding was any real progress made in this direction.

As a basis for the discussion of the relation of diet to pernicious anemia attention is called to the hypothesis of etiology which has been proposed by Castle, Townsend and Heath³² as a result of their excellent studies on the nature of the reaction between normal human gastric juice and beef muscle in producing a substance that leads to clinical improvement in pernicious anemia, similar to the effect of liver feeding. Briefly stated, the interaction of an *intrinsic factor* (an as yet unidentified substance secreted by the normal gastric mucosa and not present in patients with pernicious anemia) and an *extrinsic factor* (in the diet probably protein in nature—e.g., beef muscle—or closely related) results in a

substance (or substances) which after absorption produces a marked hematopoietic effect in pernicious anemia. *Pernicious anemia is essentially due to the lack of the intrinsic factor*. The substance resulting from the interaction of the intrinsic and extrinsic factors exists preformed in liver and certain other foods, by the feeding of which, pernicious anemia may be successfully treated.

How may diet be related to this hypothesis?

1 In the first place, Castle, Townsend and Heath³² suggest that abnormal diets may possibly have a relationship to the original gastric dysfunction in pernicious anemics. This is as yet hypothetical.

2 In the second place, there are probably a great many more *potential* pernicious anemics than those who have actually developed the disease: individuals with probably a partial or possibly even complete loss of the intrinsic gastric factor; individuals who nevertheless have not become anemic because in their diets they manage to obtain enough of the *preformed* hematopoietic substance (liver, kidney, others?) to meet their needs. The well-known familial occurrence of achylia gastrica and pernicious anemia lends support to this view. In such individuals the deprivation of certain foods might be the means of precipitating or hastening the anemia. In Germany the period of greatest food lack as a result of the war and the financial crash was the year 1923. Protein food was particularly scarce. In that year Germany recorded its highest incidence of pernicious anemia. In 1926 the incidence of the disease was

pernicious anemia patients in 1923 was seven times as great as in 1908, and three times the number in 1926^{16,33,34} when the stringency had been largely relieved. Then again, in such potential anemics a diet which has just sufficed at a given age may become inadequate in later years, for Minot³⁵ has observed that, while an average of 300 grams of liver was an adequate daily maintenance dose for pernicious anemia patients at the age of 45, those at 60 required 600 grams and at 69 well over 600 grams, probably because of diminished absorption or utilization, incident to arteriosclerosis.

3 To the above I wish to add another possibility: namely, that in rare instances an Addisonian type of blood picture may result in a patient whose diet is deficient in the *extrinsic factor*. I wish to report a patient who in the presence of free hydrochloric acid in the gastric juice, developed an Addisonian blood picture, an anemia apparently brought on by an unusual type and degree of prolonged voluntary diet restriction and in which a more liberal diet produced a typical remission. The data available are unfortunately rather scant but perhaps not wholly inadequate.

CASE REPORT

Case I. T. O., an Irishman of 50 years was admitted to the University Hospital on Sept. 20, 1921, with chief complaints of weakness, swelling of the legs and dimness of vision. At the age of 33 he had become a vegetarian in the ordinary sense of the word, using milk and eggs freely in the diet. After some years, however, he became convinced that this was inconsistent, and introduced milk and eggs. He then proceeded to distinguish between fine and gross articles, the latter being those for which he considered no use should be made as harmful.

specified, among others, peas and beans) and these in turn he decided to use very sparingly. For these and other reasons he became estranged from his wife and thereafter lived alone in an apartment where he prepared his own food. He worked long hours as a teacher and magazine writer, and eating was only of minor significance in his scheme of things. For example, he would boil a huge pot full of potatoes and spinach on Sunday and would eat these cold the rest of the week, together with plenty of fruits, raw vegetables, bread and nuts. In the past six years there had been gradually increasing distress after meals, failing vision, diminishing appetite and an increasing constipation. In the past year these symptoms had become aggravated and in addition there had developed weakness, swelling of the feet and ankles, dyspnea on exertion, and, more recently, numbness and tingling in the feet. His weight had fallen from a maximum of 125 pounds to 115. He did not complain of a sore tongue.

Physical examination showed a pale pasty-looking individual with markedly swollen legs. There was no jaundice of skin or sclerae. The tongue was smooth and pale. The spleen was not palpable. Knee jerks and Achilles jerks were preserved but diminished. Vibratory sense was unfortunately not tested. An eye examination showed optic atrophy, a central color scotoma, marked contraction of the retinal arteries, vision 3/60—(in 1916 it had been 6/6 according to the ophthalmologist's record). During the first two weeks in the hospital the temperature rose as high as 100.4° F., thereafter it remained normal. The urine had a specific gravity of 1.010, contained no sugar and no albumin, the urinary sediment showed occasional hyaline casts, no blood or pus. The feces contained no occult blood.

The blood figures are shown in table I and chart 1.

The blood picture with its high color index, red cell changes and leukopenia suggested a pernicious anemia. In view of his serious condition a transfusion was decided upon. The patient, however, refused to accept blood unless it were from another vegetarian and one who did not use to-

bacco! Iron was ordered, but unfortunately in the form of "ovoferrin", which the patient refused because of the "ovo". He did receive several hypodermics of iron and arsenic but finally refused them because of discomfort at the site of injection. He thereafter received no medication. Because it was felt that his anemia had been caused by his bad diet habits, it was decided to feed him white meat of chicken, milk, and eggs. This had to be done surreptitiously by disguising these foods in various combinations with vegetables. There resulted a marked and rapid improvement in the patient's general condition as well as in the blood picture. His vision improved to the extent that he could again read with the aid of a hand lens. The edema, obviously due to protein starvation, promptly disappeared, while his weight increased to 120 pounds. On Jan 7, 1922, the patient left the hospital and returned to his work.

For several months he continued in fair health. But he returned to his original diet habits and eventually began to fail again. A gastric analysis made in March, 1922, showed a total acidity of 30 and a free hydrochloric acid of 18. In April, 1922, the blood count had again fallen to 1,400,000 and the hemoglobin to 35 per cent. He was urged to return to the hospital, but he refused, going instead to a vegetarian sanitarium in another city where he died a few weeks later.
